**ABSTRACT**

In this study, 150 eye swabs were collected from patients suffering from conjunctivitis of both sexes admitted to Ophthalmic Unit of Hilla Teaching Hospital during the period from July to December 2020 in Hilla Province, Iraq. These eye swabs were subjected to bacterial culturing, biochemical tests, and Satellitism test using Hemin (factor X) and NAD (factor V) for isolation and identification of *Haemophilus influenzae*. The results showed that 38 (25.3%) out of 150 eye swabs were approved as *H. influenzae* strains and only 26 isolates (68.4%) were positive by using the Satellitism test. These isolates were subjected to PCR technique using *omp6* gene primer for confirming isolation of *H. influenzae*. The results revealed that only 24 (92.3%) out of 26 isolates were positive. Additionally, the PCR technique succeeded in separating these (24) isolates of *H. influenzae* into typeable and nontypeable based on the presence or absence of a capsule by using *bexA* and *bexB* genes primers. The results found that all 24 (100%) isolates did not contain *bexA* and *bexB* genes and are nonencapsulated (nontypeable) isolates.

**1. INTRODUCTION**

 Conjunctivitis is a common type of eye infection usually characterized by inflammation of conjunctivae with swelling of the conjunctival tissue, engorgement of the blood vessels, eye discharge, and irritation. Globally, conjunctivitis affects multiple subjects, and it is one of the important causes of office visits to general medical and ophthalmological clinics [1]. The commonest types of bacteria that cause bacterial conjunctivitis include *Staphylococcus aureus*, *Pseudomonas aeruginosa*, *Escherichia coli*, *Klebsiella* spp., *Streptococcus pneumoniae*, *Haemophilus influenzae*, *Proteus mirabilis*, and *Neisseria gonorrhoeae* [2]. *Haemophilus influenzae* is the causative agent and the commonest type of bacteria isolated from patients suffering from bacterial conjunctivitis [3]. It is a Gram-negative coccobacilli bacterium, and the major virulence factor is the polysaccharide capsule. Depending on the presence or absence of the capsule, *H. influenzae* strains can be subdivided into encapsulated (typeable) and nonencapsulated (nontypeable). Encapsulated strains were divided into six serotypes, ranging from A to F, and comparatively homologous irrespective of their serotype, while the nontypeable strains are genetically diverse [4]. It is a respiratory tract opportunistic pathogen and the largest contributor to invasive disease of Haemophilus. During the process of pathogenesis, adhesion plays a major role. Also, they may be diverse in structures like trimeric autotransporters “Hmw1, Hmw2, Hia, and Hap,” surface proteins, “outer membrane proteins,” including OMPs 1, 2, 4, 5, and 6, proteins E, and proteins F, as well as surface protrusions “T4SS and HIF” and the immunogenicity and potential vaccine candidates [5]. Additionally, *H. influenzae* can be classified into three major categories, including (nencapsulated, capsulated nontype b, and encapsulated type b), where type b is considered as the most virulent form [6].

The objectives of the current study are to isolate and identify *H. influenzae* from eye swabs of patients with conjunctivitis by
the traditional culture methods, Satellitism test using “X and V”
factors, and PCR technique. In addition to differentiating both
capsulated (typeable) and nonencapsulated (nontypeable) *H. influenzae*
using *bexA* and *bexB* gene primers by the PCR assay.

2. MATERIALS AND METHODS

2.1. Eye Swabs Collection and Bacterial Identification

The eye swabs were obtained from the conjunctiva of 150
patients with conjunctivitis of both sexes admitted to Ophthalmic
Unit of Hilla Teaching Hospital during the period from July to
December 2020 in Hilla Province, Babylon Governorate, Iraq.
The specimens were transported using specific transport media,
and in the laboratory, these swabs were cultured onto the surface
of blood agar, MacConkey agar, and chocolate agar. After that,
the identified bacterial colonies were subjected to Gram’s stain,
and specific biochemical tests such as “catalase, oxidase, Voges–
Proskauer, indole, urease, nitrate reduction, and carbohydrate
fermentation” were performed to reach the final identification [7].

2.2. Satellitism Test of *H. influenzae*

This test, used to determine *H. influenzae* isolates, was conducted
by mixing a loopful of suspected bacterial colonies into
approximately 2 ml of sterile saline solution. Inoculate the plates
of tryptic soy agar with the bacterial suspension by a sterile swab,
and streak a pure culture of *S. aureus* across each plate that had
been inoculated. The culture media were then incubated for 18 to
24 hours in 5% CO₂ at 37°C. Observe the suspected colonies of *H. influenzae* if the growth is seen in the agar plates as the colonies
are close to the column of *S. aureus* and the growth is greater than
that farther away from it [8].

2.3. DNA Extraction and Molecular Detection of *H. influenzae*

The DNA extraction method was performed according to the
manufacturer’s protocols of the genomic DNA purification kit
(Promega, USA). The pathogen suspected to be *H. influenzae*
isolates was subjected to conventional PCR method to detect
the specified gene amplification products of the *omp6* gene for
confirming isolation of *H. influenzae*, and the method was done as
described previously [9]. The itemized sequences of the primer sets
are illustrated in Table 1. A total volume of the reaction mixture
(20 μl) contained 5 μl of DNA template, 3 μl of each primer, 5 μl
of Green Master Mix (2×), and 4 μl of nuclease-free water. The thermal cycling condition usually starts the process with initial
denaturation steps being carried out at 95°C for 10 minutes. Next,
30 cycles consisted of a denaturation step at 95°C for 30 seconds,
annealing step at 55°C for 1 minute, and extension step at 72°C
for 2 minutes. The final extension step was at 72°C for 5 minutes.
The PCR amplification products were observed on a 1.5% agarose
gel stained with ethidium bromide for 45 minutes at 70 Volt and visualized by UV transilluminator.

2.4. Molecular Detection of *bexA* and *bexB* genes in *H. influenzae* Isolates

The PCR technique was used for differentiating *H. influenzae*
isolates into typeable and nontypeable using the primer pair with
the amplicon size specific to *bexA* and *bexB* genes. The itemized
sequences of the primer sets are illustrated in Table 1, as previously
described in [10,11] with some modifications.

The thermal cycling condition usually starts the process with the
“initial denaturation step being carried out at 95°C for 2 minutes.
Next, 30 cycles consisted of a denaturation step at 95°C for
30 seconds, primer annealing step at 54°C for 30 seconds, and
extension step at 72°C for 45 seconds. Then final extension step
was at 72°C for 5 minutes.” The PCR amplification products were
observed on a (1.5%) agarose gel stained with ethidium bromide
for 45 minutes at 70 V and visualized by UV transilluminator.

3. RESULTS

Among the 150 eye swabs obtained from patients suffering
from conjunctivitis, it was found that only 38 isolates (25.3%)
were approved as *H. influenzae*. Among these isolates, only 26
(68.4%) were positive by Satellitism test using discs of X and V
factors which are required for growth of *H. influenzae*. To confirm
isolation of the *H. influenzae*, these 26 isolates were subjected
to further detection using a molecular PCR assay to identify of
*omp6* gene, and the results revealed that only 24 (92.3%) out of 26
isolates were positive for *omp6* gene as shown in Figure 1.

The PCR method was used for differentiating all the 24 isolates of *H. influenzae*
into both encapsulated (typeable) and nonencapsulated (nontypeable) *H. influenzae* using the primer pair with
the amplicon size specific to *bexA* and *bexB* genes. The results found that all 24 isolates (100%) were negative (did not contain *bexA* and
*bexB*) genes and are considered as nonencapsulated (nontypeable)
isolates. The results of the PCR method for detection of the *bexA*
gene are shown in Figure 2.

| Genes | Primer sequence | Size of amplicon (bp) | Reference |
|-------|-----------------|-----------------------|-----------|
| *omp6* | Forward: 5ʹ-AACCTTTGCGCTACTCTG-3ʹ  
Reverse: 5ʹ-CTAACACTGCAACGCTT-3ʹ | 351 | Ueyama et al. [9] |
| *bexA* | Forward: 5ʹ-CGTTGTGATGATGGATGATCCAGAC-3ʹ  
Reverse: 5ʹ-TGCCACCATGGCTCTCTCAAAGTGATG-3ʹ | 343 | Falla et al. [10] |
| *bexB* | Forward: 5ʹ-GGTGATGATACCGTGTGTTATGCG-3ʹ  
Reverse: 5ʹ-TTGTGCCCTGTGCTGGAAGTTATG-3ʹ | 567 | Davis et al. [11] |
Figure 1: Agarose gel electrophoresis of *H. influenzae* _omp6_ gene detection. Lane M: marker with 100 bp ladder and lanes 1–3 and 5–8: positive for _omp6_ gene, while lanes 4 and 9: negative for _omp6_ gene. Amplicon size: 351 bp.

Figure 2: Agarose gel electrophoresis of *H. influenzae* _bexA_ gene detection. Lane M: marker with 100 bp ladder and lanes 1–9: negative for _bexA_ gene.

Table 2: Profile the three diagnostic methods of H. influenzae isolates.

| Test type            | No. of specimens | No. of positive results (%) |
|----------------------|------------------|----------------------------|
| Bacterial culturing  | 150              | 38 (25.3%)                 |
| Satellitism test     | 38               | 26 (68.4%)                 |
| PCR technique        | 26               | 24 (92.3%)                 |

Also, the comparison and correlation of the three methods used in the diagnosis of H. influenzae are summarized in Table 2.

4. DISCUSSION

*Haemophilus influenzae* is the most common causative organism in children who suffer from acute bacterial conjunctivitis and mostly presents as conjunctivitis-otitis media syndrome coinciding with acute otitis media [12]. The most frequent cause of bacterial conjunctivitis is *H. influenza.* Complete or partial locus for capsule production is found in some strains of *H. influenzae* but lacks a functional “bexA” gene, which encodes for a protein involved in export of capsular polysaccharides to the cell surface. These strains are nontypeable *H. influenzae* (NTHI). Sinusitis, otitis media, conjunctivitis, and chronic obstructive pulmonary disease are mucosal infections, which are mainly caused by nontypeable of *H. influenzae* strains [13].

The findings of the present study showed differences in the rate of *H. influenzae* isolation, probably explained by a variety of factors such as the age of patients, sample size, season of sampling, the type of antibiotic used in treatment, which may be linked to *H. influenzae* expressing multiple virulence factors in numerous locations on the human body as its native host, and the type of detection methods that give sensitivity and specificity in more accuracy. In contrast, the results disagree with the previous results studies reported by Rai et al. [14], which showed that the cultural method might be used for *H. influenzae* isolates at a rate of around (18.05%) by using discs of X and V factors, while another study has revealed that the *H. influenzae* can be isolated at a rate of 27.16% by the use of selective media and discs of “X and V” factors [15]. Also, the previous results recorded in Iran found that the *H. influenzae* may be isolated from eye mucus of patients suffering conjunctivitis and other different sites at a prevalence rate (31.4%), depending on their morphology and growth requirement for “X and V” factors [16].

The molecular detection method was used to confirm the diagnosis of the *H. influenzae* isolates by detecting the presence of the *omp6* gene. The *omp6* gene was only detected in 24 isolates (92.3%) of *H. influenzae* obtained from patients with conjunctivitis. Despite the fact that *H. influenzae* has a number of OMPs such as P5 and P2, unlike P2, the P6 protein has a high homology at a rate of 97% in studies of type b and NTHI amino acids, indicating that it is strongly conserved and stable [17]. A previous study had proved that NTHi OMP P6 is a possible part of the vaccine for prevention of *H. influenzae* infections [18].

Additionally, the results revealed that all 24 isolates (100%) were noncapsulated (nontypeable) isolates by using the PCR method. The obtained result is higher than the result of the other research findings obtained from Ref. [19], which indicated that NTHI isolates account for 44%–68% of bacterial conjunctivitis cases in children. Other studies discovered that the existence or absence of the *bexA* gene determined if the isolate was encapsulated or nonencapsulated by molecular PCR assay; their findings showed that the rate of NTHi was about 93.5% [20].

5. CONCLUSIONS

NTHi was an important bacterium detected in eye swabs of patients suffering from conjunctivitis of both sexes. The use of the PCR method for the identification of *H. influenzae* isolates by detecting the *omp6* gene was regarded as a faster, more sensitive, and more appropriate method than the use of traditional bacterial culturing methods and presumptive identification using X and V factor tests.

6. ACKNOWLEDGMENTS

The authors thank the reviewers for their evaluation of the manuscript.

7. AUTHORS’ CONTRIBUTION

All authors have made substantial contributions to the conception or design of the work, collection of the study samples, performing all the analysis and laboratory tests, interpretation of data for the work, preparation of the draft, revision of the article, and final approval of the version to be published.

8. CONFLICTS OF INTEREST

The authors declare that they have no conflicts of interest.

9. FUNDING

This work is self-funded.

10. ETHICAL APPROVALS

This study was approved by the Research Ethical Committee of both Ministry of Health and Environment and Ministry of Higher Education and Scientific Research in Iraq.
