Prefrontal mechanisms of behavioral flexibility, emotion regulation and value updating

Peter H Rudebeck, Richard C Saunders, Anna T Prescott, Lily S Chau & Elisabeth A Murray

Two ideas have dominated neuropsychology concerning the orbitofrontal cortex (OFC). One holds that OFC regulates emotion and enhances behavioral flexibility through inhibitory control. The other ascribes to OFC a role in updating valuations on the basis of current motivational states. Neuroimaging, neurophysiological and clinical observations are consistent with either or both hypotheses. Although these hypotheses are compatible in principle, we present results supporting the latter view of OFC function and arguing against the former. We found that excitotoxic, fiber-sparing lesions confined to OFC in monkeys did not alter either behavioral flexibility, as measured by object reversal learning, or emotion regulation, as assessed by fear of snakes. A follow-up experiment indicated that a previously reported loss of inhibitory control resulted from damage to nearby fiber tracts and not from OFC dysfunction. Thus, OFC has a more specialized role in reward-guided behavior and emotion than has been thought, a function that includes value updating.

The orbital prefrontal cortex (OFC) is seen as a central node in the emotional circuits of the brain. Profoundly altered regulation of emotions is a hallmark of damage or dysfunction in OFC. At the extremes, patients with damage to the OFC show ‘acquired sociopathic’ behavior. Monkeys with lesions of OFC similarly show altered emotional responsiveness to fear-inducing stimuli. OFC is also critical for behavioral flexibility. Neuropsychological studies have repeatedly found that damage to OFC leads to an inability to rapidly alter object–reward associations, as assessed in the object reversal learning task. This influential result has achieved classic status and has been replicated many times in humans, monkeys, rodents and other mammals.

In part because patients with OFC damage show a correlation between the severity of impairments on the object reversal learning task and the degree of emotional disruption, some theories posit that emotion regulation and behavioral flexibility reflect a single, OFC-dependent process corresponding to inhibitory control. This ‘inhibitory control’ hypothesis has had a wide-ranging impact, influencing thinking not only about how the prefrontal cortex integrates emotion and cognition but also about the pathophysiology of several psychiatric and neurological disorders.

An alternative view of OFC function has also found support. It holds that OFC is critical for representing and updating specific outcome expectations to guide decisions. This idea agrees with neurophysiological and neuropsychological studies of OFC, which have emphasized the function of this area in encoding specific stimulus–outcome expectancies as well as revaluing such expectancies on the basis of motivational states.

These two hypotheses about OFC function—inhibitory control and updating valuations—are not incompatible, of course, and results from neuroimaging and neurophysiology agree with both. However, recent results from neuropsychology have cast doubt on the former. In particular, two recent studies have found that partial lesions of OFC have no effect on object reversal learning, long assumed to assess behavioral flexibility and inhibitory control. Because these experiments involved excitotoxic lesions, which spared fibers passing through or near OFC, we investigated the possibility that the ‘classic’ effects of OFC damage have depended on inadvertent damage to fiber tracts running near or through OFC and not on the function of OFC per se. In so doing we reassessed the two hypotheses of OFC function outlined above. Specifically, we tested behavioral flexibility, emotion regulation and revaluation in monkeys that had received complete, excitotoxic, fiber-sparing lesions of OFC.

Here we report that damage limited to neurons within OFC does not produce the deficits in behavioral flexibility and emotion regulation that are observed after aspiration lesions of this region. Instead, our data show that OFC in monkeys is necessary for the ability to revalue objects in line with changing biological needs. A further experiment confirmed that the ‘classic’ effects of OFC lesions depend on damage to proximate fiber tracts.

RESULTS
OFC, behavioral flexibility and emotion regulation
We tested monkeys with complete, bilateral excitotoxic lesions of OFC (OFC<sub>EXC</sub> n = 7, Fig. 1) and a group of unoperated controls (CON<sub>EXC</sub> n = 12) on the key tests of behavioral flexibility and emotion regulation used in earlier studies. On the basis of MRI assessment, we estimated that the injections of excitotoxins destroyed a mean of 77.2% (range, 64.3–96.3) of OFC (Supplementary Table 1). Inadvertent damage to adjacent prefrontal cortical and subcortical structures was minimal. The extent and location of the lesions matched that used in earlier studies that had used aspiration lesions of OFC (OFC<sub>ASP</sub>; one-way...
Figure 1  Excitotoxic lesions of OFC.
Left panel, the extent of the intended lesion (shaded region) on a ventral view (left) and on standard coronal sections (right) through the frontal lobe of a macaque brain. The lesions correspond approximately to Walker’s areas 11, 13 and 14. Numerals indicate the distance in mm from the interaural plane. Right panel, coronal images at corresponding levels taken from T2-weighted MRI scans obtained within 1 week of surgery from OFCEXC subjects 3 and 6. White hypersignal (set off by arrowheads) is associated with edema that follows injections of excitotoxins and indicates the extent of the lesion. Left and right sides of the MR images are from different scans and have been placed together for ease in viewing. Scale bar, 5 mm.

ANOVA, total lesion volume, OFCEXC versus OFCASB, F1,9 = 0.4, P = 0.85) and that had produced severe impairments in behavioral flexibility and emotion regulation4,9. The methods used to assess reward-guided behavior in the present and previous studies were virtually identical (see Online Methods); accordingly, we were able to directly compare the scores of monkeys in the present study with those of monkeys with aspiration lesions of OFC (OFCASB n = 3) and their corresponding controls (CONASP, n = 10)4,9.

We first sought to determine the effect of excitotoxic lesions of OFC on object reversal learning, a widely used test of behavioral flexibility that has been linked to inhibitory control10,16. Initially monkeys learned to discriminate a single pair of objects, novel at the start of testing, for a food reward. After monkeys had met the learning criterion on this initial object discrimination problem, the contingencies were reversed (that is, the rewarded object now became the unrewarded item of the pair, and vice versa) and the monkeys were trained until they reached the same criterion as before. This procedure was repeated until a total of nine serial reversals had been completed. The four groups of monkeys learned the initial discrimination at a similar rate (Fig. 2; one-way ANOVA, F3,28 = 0.56, P = 0.65). In addition, all monkeys, both operated and controls alike, made fewer errors as they completed more reversals (Fig. 2; repeated measures ANOVA, effect of reversal, F8,224 = 15.72, P = 0.001). Over the course of nine serial reversals, monkeys with excitotoxic lesions of OFC switched their responses to the rewarded object as quickly as controls, but they were markedly different from monkeys with aspiration lesions of OFC (effect of group, F3,28 = 15.25, P < 0.001; post hoc tests, OFCEXC versus OFCASB, P < 0.001; OFCEXC versus either CONEXC or CONASP, P = 1.00).

Given this unexpected result, we further probed whether monkeys with excitotoxic lesions of OFC used both positive (correct) and negative (error) feedback in a manner similar to that of the controls. This trial-by-trial analysis, which is arguably more sensitive than our main measure, also showed no effect of the excitotoxic OFC lesions on monkeys’ choices (repeated measures ANOVA, effect of group F3,28 = 5.91, P = 0.003; post hoc tests, OFCEXC versus CONEXC or CONASP, P = 1.00). By contrast, monkeys with aspiration lesions of OFC differed markedly from controls (CONEXC, P = 0.002; CONASP, P = 0.005; Supplementary Fig. 1a) and from monkeys with excitotoxic lesions of the OFC (P = 0.011). These data indicate that excitotoxic lesions of OFC do not simply produce a milder deficit than aspiration lesions. Thus, at least in macaques, OFC is not necessary for the ability to flexibly assign rewards to particular objects, as required by the object reversal task.

Next we assessed emotion regulation in these same monkeys. Monkeys fear artificial or real snakes, even when they have not encountered them previously31, and aspiration lesions of OFC blunt such emotional responses, rendering monkeys less fearful of snakes4,32. To assess emotional responsiveness, we presented fear-inducing stimuli (toy spider or snake) and neutral objects, one at a time, inside a transparent plastic box with a food reward placed on the back edge of the box. The dependent measure was the time taken by monkeys to reach over the object to retrieve the food reward. On some trials there is a conflict between approach responses elicited by a motivational incentive, the food, and withdrawal responses engendered by a fear-inducing stimulus. On the basis of earlier results, we predicted that intact animals would show a greater latency to retrieve the food on trials with fear-inducing objects than on those with neutral objects. Because differences in testing protocols preclude direct comparison of excitotoxic and aspiration lesions of OFC, we restrict comparisons to include only concurrently run controls (CONEXC).

Monkeys with excitotoxic OFC lesions and unoperated controls readily retrieved the food reward in the presence of neutral objects but took increasingly longer in the presence of progressively more

Figure 2  Excitotoxic lesions of OFC did not disrupt object reversal learning. The plot shows the number of errors before reaching criterion made by monkeys during acquisition (ACQ) and the nine subsequent serial reversals (1–9) in the object reversal learning task. In contrast to monkeys with aspiration lesions of OFC, monkeys with excitotoxic lesions of OFC scored in the same range as unoperated controls. CONASp and CONEXC, unoperated control monkeys, OFCASp, monkeys with bilateral aspiration lesions of the orbital prefrontal cortex; OFCEXC, monkeys with bilateral excitotoxic lesions of the orbital prefrontal cortex. Data for groups OFCASp and CONASP are from an earlier study9. Error bars show s.e.m.
Anxiogenic objects (repeated measures ANOVA, effect of object type, $F_{5,85} = 45.3$, $P < 0.001$, Fig. 3a). Monkeys with excitotoxic lesions of OFC were just as fearful of the snake and spider stimuli as the controls, as measured by their retrieval latencies (group by object-type interaction $F_{5,85} = 0.45$, $P = 0.74$; effect of group, $F_{1,17} = 0.008$, $P = 0.93$). This is in contrast to the behavior of monkeys with aspiration lesions of OFC, who fail to inhibit food retrieval responses in the presence of the fear-inducing objects. Thus, excitotoxic lesions of OFC in macaques do not alter emotion regulation, at least in the domain tested.

**OFC and the ability to revalue objects**

To determine the contribution of the OFC to the updating of object-outcome value, we evaluated the monkeys’ behavior on an object reinforcer devaluation task. In contrast to object reversal learning, this task measures the ability of monkeys to flexibly choose between rewarded objects on the basis of the biological value of associated foods (see Online Methods). Monkeys learned 60 object discrimination problems in which the positive objects of each pair were rewarded consistently with either food 1 (30 objects) or food 2 (30 objects). We then used a selective satiation procedure intended to devalue one of the two foods to test whether monkeys could update the value of specific object-outcome associations. In critical test sessions comprised of probe trials, monkeys were presented with pairs of objects associated with either food 1 or food 2 and were able to choose between the objects based on their subjective preferences. To determine the degree to which monkeys adaptively shifted their choice of objects following reinforcer devaluation, we computed a difference score (object choices after satiation relative to object choices during baseline). Higher difference scores reflect a greater shift from baseline after selective satiation and therefore a greater sensitivity to the present value of the foods. In keeping with previous studies, we conducted two devaluation tests (see Online Methods). To allow comparison with previously studied groups (CONASP and OFCASP), we compare group scores only on reinforcer devaluation test 2. Irrespective of which test we analyzed, the statistical outcome was the same (Supplementary Fig. 2a).

In sessions after selective satiation, unoperated controls (CONEXC and CONASP) adaptively shifted their choices relative to baseline sessions; specifically, they selected objects associated with the non-sated food on a high proportion of trials, a phenomenon known as the devaluation effect. By contrast, both groups of monkeys with lesions of OFC failed to shift their object choices to the same degree as controls after selective satiation (one-way ANOVA, $F_{3,28} = 7.31$, $P = 0.001$; post hoc tests, OFCExc versus CONEXC, $P = 0.003$ or CONASP, $P = 0.008$; OFCExc versus OFCASP, $P = 1.00$; Fig. 3b). Thus, like monkeys with aspiration lesions of OFC, monkeys with excitotoxic lesions of OFC were unable to link objects with the present biological value of associated food rewards. Control procedures showed that the impairment was unlikely to be due to factors such as gross changes in visual perception, motivation, food preferences or an inability to discriminate between the two foods (Supplementary Fig. 2b).

In addition to showing a function for OFC in linking objects with the value of specific outcomes and/or using that information to guide choices, these data also indicate that the lesions were effective.

**White matter near OFC, behavioral flexibility and emotion**

Taken together, the pattern of spared and impaired abilities in macaques with the two types of OFC lesions (either excitotoxic or aspiration) reveals that deficits in emotion regulation and behavioral flexibility observed after aspiration lesions of OFC are related but that they do not depend on OFC. Instead, the ‘classic’ deficits reported in previous studies may be due to inadvertent damage to neuronal projection fibers passing nearby or through OFC en route to other regions, either alone or in concert with damage to the neurons residing in OFC. Notably, cortical and subcortical structures in the medial temporal lobe contain neurons that project to the prefrontal cortex, and these projections course near the posterior and ventromedial portions of OFC by way of the uncinate fascicle, as well as the extreme capsules. Furthermore, neurons in OFC send efferent projections to many targets, including the ventral striatum and medial thalamus, and these connections also pass near the posterior OFC. If impairments seen after aspiration lesions of OFC are due to
damage to fibers of passage, then an aspiration lesion limited to the posterior OFC should reproduce alterations in emotion regulation and reversal learning performance, regardless of the exact site(s) of origin or termination of those fibers.

To test this hypothesis, we removed by aspiration a narrow strip of cortex, oriented in the mediolateral plane and situated at the posterior boundary of our OFC lesion, in a total of three monkeys from the CON_{ASL} (n = 2) and OFC_{ASL} (n = 1) groups (group OFC_{STRIP}). We refer to these surgical removals as strip lesions. Lesions were assessed using T1-weighted MRI scans and found to reliably destroy a strip of cortex in posterior OFC; the lesion involved portions of areas 13l, 13m, 13a and 14c (Fig. 4)\textsuperscript{35}. We retested these monkeys on the object reversal learning task and then the emotional responsiveness task. Their scores were compared with those of the original unoperated control group (CON_{STRIP}, n = 10) and the monkeys with aspiration lesions of OFC and their controls (OFC_{ASP} and CON_{ASP}).

All groups performed similarly when acquiring the initial discrimination problem in the object reversal learning task (Fig. 5a; \( F_{3,22} = 0.15, P = 0.93 \)). When the reward contingencies were reversed, however, monkeys with either strip lesions of the posterior OFC or complete aspiration lesions of OFC made many more errors than controls (repeated measures ANOVA, effect of group, \( F_{3,22} = 16.67, P < 0.001 \); post hoc tests, OFC_{STRIP} versus CON_{STRIP}, \( P = 0.001 \); OFC_{STRIP} versus OFC_{ASP}, \( P = 0.021 \); OFC_{ASP} versus CON_{STRIP} or CON_{ASP}, \( P < 0.0025 \)). Monkeys with either strip lesions or aspiration lesions performed similarly (OFC_{STRIP} versus OFC_{ASP}, \( P = 1.00 \)). Notably, the difference between monkeys with strip lesions of the posterior OFC and unoperated controls occurred despite the previous exposure of the OFC_{STRIP} group to object reversal learning, which might be expected to improve performance. Further trial-by-trial analyses with data collapsed across reversals found that monkeys with strip lesions of the posterior OFC did not benefit from either correctly or incorrectly performed trials to the same degree as unoperated controls (effect of group, \( F_{3,22} = 5.74, P = 0.005 \); least squares difference post hoc tests, OFC_{STRIP} versus CON_{STRIP}, \( P = 0.022 \); OFC_{STRIP} versus OFC_{ASP}, \( P = 0.034 \); Supplementary Fig. 1b). Notably, the scores of monkeys with strip lesions of posterior OFC did not differ from those of monkeys with complete aspiration lesions of OFC (\( P = 0.426 \)).

Similarly, monkeys with strip lesions of the posterior OFC showed altered emotional responses to fear-inducing stimuli by comparison to unoperated controls (repeated-measures ANOVA, group by object-type interaction \( F_{2,22} = 4.56, P = 0.022 \); effect of group, \( F_{1,11} = 6.01, P = 0.031 \); Fig. 5b). This difference was primarily driven by scores on trials with the moving snake; monkeys with strip lesions of the posterior OFC readily retrieved the food reward in the presence of the normally anxiogenic moving snake object, in contrast to unoperated controls (moving snake trials, repeated measures ANOVA, effect of group \( F_{1,11} = 7.51, P = 0.019 \)). Given that only a small portion of OFC was removed in the strip lesions, these data support the idea that damage to fiber pathways is sufficient to produce deficits observed after complete aspiration lesions of OFC.

**DISCUSSION**

We assessed monkeys with excitotoxic lesions of OFC on two tests of inhibitory control (object reversal learning and snake fear) and one of updating object–outcome expectancies (reinforcer devaluation). Unlike aspiration lesions of OFC, damage limited to cells in this area but sparing fibers did not affect either behavioral flexibility, as measured by object reversal learning, or emotion regulation, as measured by snake fear. These excitotoxic lesions did, however, cause the same impairment in updating valuations that follows aspiration lesions of OFC. In a follow-up experiment, aspiration of a narrow strip of cortex in the posterior OFC reproduced the often-replicated impairments in object reversal learning and the blunting of snake fear caused by aspiration lesions of the entire OFC.

Taken together, these findings show that inadvertent damage to fibers passing near or through OFC causes the impairments in behavioral flexibility and emotion regulation typically attributed to OFC. The results also support the idea that the OFC performs a more specific function in reward-guided behavior and emotion than thought, and they indicate that this function includes the updating of object valuations according to current motivational states. It could be argued that the pattern of results after excitotoxic OFC lesions—impairment on reinforcer devaluation but not on object reversal learning and emotional reactivity—simply reflects a difference in the sensitivity of the tasks to OFC damage. Against this idea, however, we note that lesions of the ventral prefrontal cortex impair reversal learning but not reinforcer devaluation\textsuperscript{36}. Thus, the devaluation task is not intrinsically more sensitive to prefrontal cortex damage.

Although our results come from macaque monkeys, there is reason to believe that this conclusion applies to humans as well\textsuperscript{37}. Given that damage to structures in the temporal lobe leads to deficits in object reversal learning and emotional responses like those observed after OFC damage\textsuperscript{38,39}, it seems likely that temporal–frontal interactions underlie both flexible responding in reversal learning and regulation of emotional responses to artificial and real snakes and spiders. Many of the relevant temporal areas project to the medial frontal cortex by way of the uncinate fascicle\textsuperscript{34}. Thus, it is possible that disruption of white matter pathways linking the temporal and medial frontal cortex is responsible for the deficits that classically follow aspiration lesions of OFC. Consistent with this idea, lesions of one part of the medial frontal cortex in macaques, the anterior cingulate cortex (ACC), mildly disrupt object reversal learning\textsuperscript{40}. The OFC aspiration and ACC lesion groups have in common the inability to sustain the correct choice of object after a reversal.

**Figure 5** Monkeys with aspiration lesions of a narrow strip of posterior OFC, like monkeys with complete aspiration lesions of OFC, were impaired on object reversal learning and showed reduced emotional responsiveness. (a) When retested on object reversal learning, monkeys with a strip lesion of the posterior OFC (OFC_{STRIP}) performed significantly worse than unoperated controls (CON_{STRIP}). Plot shows number of errors before reaching criterion made by monkeys during acquisition (ACQ) and the nine subsequent serial reversals (1–9) in the object reversal learning task. Error bars show s.e.m. (b) When retested on responses to neutral and fear-inducing objects, monkeys with a strip lesion of the posterior OFC showed reduced emotional responses relative to controls. This pattern matched that seen for monkeys with complete aspiration lesions of OFC. Symbols represent the scores of individual monkeys. Error bars show s.e.m.
Because the effects of OFC and ACC aspiration lesions on object reversal learning differ both quantitatively and qualitatively, however, damage to temporal–frontal connections directed to ACC cannot provide a complete account of the disconnection. An alternative possibility is that the deficits result from a more widespread temporal–frontal disconnection, one involving all of the medial frontal cortex and the ventral prefrontal cortex as well. This idea is consistent with identified contributions of the ventral prefrontal cortex to object reversal learning. Finally, aspiration lesions of OFC may damage several circuits passing near or through posterior OFC. Indeed, this region seems to be a bottleneck not only for fibers passing between the temporal and frontal lobes but also for fibers serving broadly directed neurotransmitter systems.

One outstanding question is why our results seem to diverge from those reported in rodents and New World monkeys. The deficits in rodents and New World monkeys reported after OFC lesions are qualitatively and quantitatively different from those seen in macaques. Specifically, aspiration lesions of the OFC in macaques have a long-lasting effect on reversal learning performance, but this effect only becomes apparent around the third or fourth serial reversal. By contrast, reversal learning deficits in rodents and New World monkeys are often transient and limited to the first few reversals (for example, ref. 43). It may be that different species learn or solve stimulus reversal tasks in slightly different ways or using different cognitive strategies. In addition, tasks are often tailored to individual species with respect to the cognitive demands of the task (for example, number of reversals performed) or the sensory modality tested (for example, odor reversal learning for rodents versus visual reversal learning in macaques), factors that hamper cross-species comparisons.

Irrespective of these differences, one possibility is that the divergence between our findings and those from rodents may reflect differences in the expansion of the prefrontal cortex across species during their prolonged period of independent evolution. Such differences could affect the dependence on the OFC for adaptive stimulus–reward–related functions. In this view, the OFC in an intact macaque brain would be involved in reversing stimulus–reward associations to a minor extent but would not be necessary for this function. When the OFC is unavailable, stimulus–reward contingency and reversal in macaques could be carried out by alternative brain structures such as the amygdala, ventral striatum and other parts of the prefrontal cortex. By contrast, in rodents, the OFC might be more important for all stimulus–reward–related functions, including reversing stimulus–reward associations.

It is more difficult, however, to account for the conflicting data from New World monkeys, specifically marmosets. In primates, the expansion of the prefrontal cortex occurred in steps, and at least some of that expansion occurred in parallel in New World and Old World monkeys. One possibility is that parts of the prefrontal cortex developed divergent functions between New and Old World monkeys. Another is that the apparent difference in the effects of OFC lesions in New and Old World monkeys reflects the distinct foraging niches of the two species studied (Callithrix jacchus and Macaca mulatta). Common marmosets feed mainly on tree gums and insects, which requires patient foraging, whereas rhesus monkeys feed on fruit, seeds, roots, buds, bark and cereals, foods obtained by more active foraging.

Our results have implications for psychiatry, computational modeling and theories of prefrontal cortex function. First, partly because of deficits in reversal learning and emotion regulation, several psychiatric disorders have been attributed to dysfunction of OFC, including major depression, obsessive–compulsive disorder and psychopathy. Given our finding that the reversal and emotion regulation impairments do not result from damage to OFC neurons, the association among inhibitory control, the OFC and psychiatric disorders needs to be reassessed.

Second, the ability to alter object–reward associations rapidly has often served as a starting point for hierarchical models of prefrontal cortex. Narrowing the range of functions attributed to OFC should contribute to more accurate computational models of prefrontal cortex and its role in the processing of rewards and risks.

Third, for decades, OFC has been held to exert inhibitory control over behavior. Although evidence in opposition to this view has been gradually accruing, our findings make it clear that inhibitory control is not the purview of OFC. Recent reconsiderations of prefrontal cortex function have led to the same conclusion. In agreement with evidence from rats, monkeys and humans, we find OFC to instead represent specific outcome expectations. These representations include the sensory properties and the motivational value of specific outcomes, such as foods, punishers and social signals, all updated in terms of biological needs based on the animal’s current state. Thus, OFC enhances fitness by allowing an informed judgment about the relative merits of choices, in the contexts in which they occur.

Subjects. Nineteen adult rhesus monkeys (Macaca mulatta), three female, served as subjects. All animals were naive at the start of the experiment, and all experiments were conducted during the light cycle of the day. For the first experiment, 7 monkeys sustained bilateral excitotoxic lesions of OFC (group OFCSTRIP) and the remaining 12 were retained as unoperated controls (group CON). Monkeys were randomly assigned to each group. For the second experiment, a pseudorandomly selected subset of the monkeys from experiment 1 were given ‘strip’ lesions of the posterior OFC (OFCSTRIP). The data from four of the unoperated controls have been previously published[7]. Data from 13 monkeys, 3 with aspiration lesions of OFC and 10 unoperated controls, from two previous studies are also included for comparison[8,9,29,51]. No statistical test was run to determine the sample size. The sample sizes we chose are similar to those used in previous publications.

Behavioral testing. After surgery, all animals were habituated to the WGTA and were allowed to retrieve food from the test tray. After preliminary training and initial food preference testing, monkeys either received excitotoxic lesions of OFC or were retained as unoperated controls. Following surgery, monkeys were tested on reinforcer devaluation test 1, emotional response test 1, reinforcer devaluation test 2, object reversal learning and then emotional test 2. The testing order was similar to previous experiments from our laboratory. In the case of the monkeys that received OFCSTRIP lesions, surgery was conducted at the conclusion of the five initial tests. Monkeys were then retested on object reversal learning and emotional test 2. Testers conducting the behavioral experiments were, where possible, blind to group assignments.

Food preference testing. After habituation to the WGTA, each monkey’s preference for six different foods was assessed over a 15-d period. Each day monkeys received 30 trials consisting of pairwise presentation of the six different foods, one each in the left and right wells of the test tray. The left-right position of the foods was counterbalanced. Preferences were determined by analyzing choices between each of the 15 possible pairs of foods over the final 5 d of testing.

Reinforcer devaluation. The behavioral methods used were similar to those reported before[6], enabling direct statistical comparisons. The procedure used object discrimination learning, which set up particular object-outcome associations, followed by reinforcer devaluation tests, in which probe trials gauged the monkeys’ abilities to link objects with present food value.

Object discrimination learning. Monkeys were trained to discriminate 60 pairs of novel objects. For each pair, one object was randomly designated as the positive object (S+, rewarded) and the other was designated as negative (S−, unrewarded). Half of the positive objects were baited with food 1. The other half were baited with food 2. For each monkey, the identity of foods 1 and 2 was based on the monkey’s previously determined food preferences. The foods selected were those that the monkey valued highly and that were roughly equally palatable as judged by choices in the food preference test.

On each trial, monkeys were presented with a pair of objects, one each overlying a food well, and were allowed to choose between them. If they displaced the S+ they were allowed to retrieve the food. The trial was then terminated. If they chose the S−, no food was available, and the trial was terminated. The left-right position of the S+ followed a pseudorandom order. Training continued until monkeys attained the criterion of a mean of 90% correct responses over 5 consecutive days. (that is, 270 correct responses or greater in 300 trials).

Reinforcer devaluation test 1. Monkey’s object choices were assessed under two conditions: in normal (baseline) conditions or after one of the foods was devalued. On separate days we conducted four test sessions, each consisting of 30 trials. Only the positive (S+) objects were used. On each trial, a food-1 object and a food-2 object were presented together for choice; each object covered a novel object. For each pair, one object was randomly designated as the positive object (S+, rewarded) and the other was designated as negative (S−, unrewarded). Half of the positive objects were baited with food 1. The other half were baited with food 2. For each monkey, the identity of foods 1 and 2 was based on the monkey’s previously determined food preferences. The foods selected were those that the monkey valued highly and that were roughly equally palatable as judged by choices in the food preference test.

On each trial, monkeys were presented with a pair of objects, one each overlying a food well, and were allowed to choose between them. If they displaced the S+ they were allowed to retrieve the food. The trial was then terminated. If they chose the S−, no food was available, and the trial was terminated. The left-right position of the S+ followed a pseudorandom order. Training continued until monkeys attained the criterion of a mean of 90% correct responses over 5 consecutive days. (that is, 270 correct responses or greater in 300 trials).

Reinforcer devaluation test 2. Object choices in the food preference test were assessed under two conditions: in normal (baseline) conditions or after one of the foods was devalued. On separate days we conducted four test sessions, each consisting of 30 trials. Only the positive (S+) objects were used. On each trial, a food-1 object and a food-2 object were presented together for choice; each object covered a novel object baited with the appropriate food. With the constraint that a food-1 object was always paired with a food-2 object, the object pairs were generated randomly for each session.

Before two of the test sessions, a selective satiation procedure, intended to diminish the value of one of the foods, was conducted. For the other two test sessions, which provided baseline scores, monkeys were not sated on either food before being tested. The order in which the test sessions occurred was the same for all monkeys and was as follows: (i) baseline test 1; (ii) food 1 devalued by selective satiation before test session; (iii) baseline test 2; (iv) food 2 devalued by selective satiation before test session.

For the selective satiation procedure, a food box filled with a preweighed quantity of either food 1 or food 2 was attached to the front of the monkey’s home cage.
The monkey was given a total of 30 min to consume as much of the food as it wanted, at which point the experimenter started to observe the monkey’s behavior. More food was provided if necessary. The selective satiation procedure was deemed to be complete when the monkey refrained from retrieving food from the box for 5 min. The amount of time taken in the selective satiation procedure and the total amount of food consumed by each monkey was noted. The monkey was then taken to the WGTA within 10 min and the test session conducted.

Reinforcer devaluation test 2. A second devaluation test, identical to the first, was conducted between 26 and 77 d after reinforcer devaluation test 1. Monkeys were retrained on the same 60 pairs to the same criterion as before. After relearning, the reinforcer devaluation test was conducted in the same manner as before.

Food choices after selective satiation. Shortly after reinforcer devaluation test 2, we assessed the effect of selective satiation on the monkey’s choices of foods alone. This test was conducted to evaluate whether satiety transferred from the home cage to the WGTA and whether behavioral effects of the lesion (if any) were due to an inability to link objects with food value, as opposed to an inability to discriminate the foods. This test was identical to both reinforcer devaluation tests 1 and 2, but with the difference that no objects were presented over the two wells where foods were placed. On each trial of the 30-trial sessions, monkeys could see the two foods and were allowed to choose between them. As was the case for reinforcer devaluation tests 1 and 2, there were four critical test sessions; two were preceded by selective satiation and two were not.

Emotional responsiveness test. Monkeys were pretrained until they readily retrieved a food reward from the top back edge of the Plexiglas box. Two emotional response tests were conducted. In the first test, eight neutral objects and two fear-inducing objects (static rubber spider and snake), all novel, were presented inside the Plexiglas box, one object per trial. Each test session comprised ten 30-s trials, each separated by 20 s. In the second test, ten novel objects, including eight neutral objects and two fear-inducing objects (moving spider and snake), were presented. As in test 1, the objects were presented for a total of five consecutive sessions. For both tests, sessions were run once every other day. The two tests were combined for analysis, as monkeys showed consistent food-retrieval latencies on trials with neutral objects (neutral objects, effect of test, $F_{1,17} = 3.84$, $P = 0.067$). The food-retrieval latencies (that is, time that monkeys took to retrieve the food reward) were determined offline using frame-by-frame video analysis. Latencies for each trial were calculated by determining the difference between the trial start and retrieval times.

Object reversal learning. A single pair of objects, novel at the start of testing, was used throughout object reversal learning. To prevent object preferences from biasing learning scores, both objects were either baited (for half the monkeys in each group) or unbaited on the first trial of the first session of acquisition of the object discrimination. If the object chosen on the first trial was rewarded, it was designated the S+; if not, it was designated the S−. Through trial and error, monkeys learned which object was associated with a food reward. Monkeys were tested for 30 trials per daily session for 5 or 6 d per week. Criterion was set at 93% (that is, 28 correct responses in 30 trials) for 1 d followed by at least 80% (that is, 24/30) the next day. Once monkeys had attained criterion on the initial object discrimination problem, the contingencies were reversed and animals were trained to the same criterion as before. This procedure was repeated until a total of nine serial reversals had been completed.

Data analysis. The data were analyzed in SPSS statistical software using one-way or repeated-measures ANOVA (two-tailed) with Hynh-Feldt correction and, where appropriate, with tests (emotional response test (neutral object comparison), 2 levels), object type (emotional response test, 6 levels), session (emotional response test, 5 levels), reversal (object reversal learning, 9 levels) as within-subject factors and group (2/4 levels) as a between-subjects factor. Further post hoc analyses with Bonferroni correction were used, unless otherwise stated, to explore any significant main effects or interactions ($P < 0.05$).
