Abstract
The aim of this study is to develop a recovery system of platinum group metals (PGMs), such as palladium, platinum, and rhodium from wastewaters that contain [PdCl₄]²⁻, [PtCl₆]²⁻ or [RhCl₆-(H₂O)₆]³⁻ ions. A built-in electromotive force from a microbial fuel cell (MFC) was utilized for recovering the PGMs from its cathode chamber under the biofilm-coated anode. After 40 hours of reaction, the obtained Pd, Pt, and Rh recovery efficiencies from MFC cathodes with an initial concentration of 200 ppm were 99.2%, 99.5%, and 98.7%, respectively. The maximum power density of 7.03 W/m² with a fill factor of 0.638 was achieved at 1000 ppm Pd²⁺ catholyte concentration under the experimental range. Using an initial catholyte concentration of 500 ppm for comparison, the maximum power density that was achieved was 4.22 W/m² for [PdCl₄]²⁻, 5.04 W/m² for [PtCl₆]²⁻, and 2.44 W/m² for [RhCl₆-(H₂O)₆]³⁻, respectively. Finally, the electrical energy generation rate was obtained from discharging curves and remaining concentration data in the order of Pd-MFC (39.2 Wh/kg) > Rh-MFC (35.1 Wh/kg) > Pt-MFC (17.2 Wh/kg). The metals recovered on the electrode surface were found to be pure based on the SEM micrographs and EDS analysis.

Introduction
Platinum group metals (PGMs) are widely used not only in healthcare, jewelry, machine, and also in the chemical industry such as catalysts for chemical reactions, electrical, electronic industries and corrosion resistant materials. However, the demand for PGMs has not been balanced by supply due to consumed resources. Also, there are no alternatives to these costly metals. The production of PGMs from secondary and technogenous materials is becoming more demanding. Thus, recycling of spent catalysts, electronic scrap, wastes of non-ferrous metals and exhausted nuclear fuel is a matter of high importance [1]. The recovery of precious metals, such as palladium, platinum and rhodium, which belong to the PGMs, is even more economical and attractive. The increasing demand for catalytic metals and the limited resource for precious metals makes the recovery of PGMs a strategic topic that has received a great deal of attention in the past decades [2]. Thus, considerable attention is given to the possibility of recovering dissolved platinum, palladium, and rhodium ions from abundant wastes, such as spent electroless plating solutions, printed circuit boards and spent nuclear fuels. Furthermore, current pyrometallurgical and hydrometallurgical recycling processes contribute to the (growing) environmental concerns and need to be replaced by some more environmentally friendly technologies [3], such as microbial fuel cell (MFC) techniques [4]. MFCs has several advantages over other recovery techniques because they are cost-effective, require less energy, cause less pollution and raise less anode corrosion, and recovers both materials and electrical energy. Highly pure metal state Pd, Pt and Rh can be recovered from the cathode chamber of MFC. The cathode chamber is separated by a membrane from the anode chamber containing biofilms and organic electron donors, generating electrical energy as a byproduct. Pd⁴⁺ as [PdCl₄]²⁻, Pt⁴⁺ as [PtCl₆]²⁻, and Rh³⁺ as [RhCl₆-(H₂O)₆]³⁻ function as potential electron acceptors in the cathode chamber of the MFC because of their high standard reduction potentials.

The electrochemical reactions and standard reduction potentials of precious metal ions of interest in this study with respect to standard hydrogen electrode (SHE) at 25°C are as follows:

\[
\text{NADH} = \text{NAD}^+ + 2\text{H}^+ + 2e^- \quad (\text{for example, a ratio of } [\text{NADH}] / [\text{NAD}^+] = 0.1 \text{ in biofilm})
\]

\[
E^c = -0.281 \text{ V} \quad (1)
\]

\[
[\text{PdCl}_4]^{2-} (\text{aq}) + 2e^- = \text{Pd(s)} + 4\text{Cl}^- (\text{aq}) \quad E^c = 0.59 \text{ V} \quad (2)
\]

Nicotinamide adenine dinucleotide (NADH) is produced in the citric acid cycle (CAC) of the bacteria metabolizing carbonaceous materials, such as acetate and glucose. It is oxidized to transfer electrons to the anode following Eq. (1) as an electron donor, and precious metal ions can be used as electron acceptors to be reduced at the cathode following Eq. (2). From these two equations, the built-in electromotive force generated is calculated to be 0.87 V. E^c is utilized for recovering the PGMs from its cathode chamber under the biofilm-coated anode.

\[
[\text{PtCl}_6]^{2-} (\text{aq}) + 2e^- = [\text{PtCl}_4]^{2-} (\text{aq}) + 2\text{Cl}^- (\text{aq}) \quad E^c = 1.011 \text{ V} \quad (3)
\]

\[
[\text{PtCl}_6]^{2-} (\text{aq}) + 2e^- = \text{Pt(s)} + 4\text{Cl}^- (\text{aq}) \quad E^c = 0.847 \text{ V} \quad (4)
\]

From Eq. (3), the electromotive force is known to be E^c of 1.292 V, and from Eq. (4) it is calculated to be E^c of 1.128 V, which means that the Pt recovery reaction occurs through two two-electron processes. Finally, Rh⁶⁺ is the principal oxidation state among the oxidation states of the complexes usually dominating in chloride solutions. Rhodium recovery seems complex because there exists seven different chloro-complexes depending upon HCl concentration [5]. In most solutions there exist at least two species. These chloro complexes undergo aquation as below:

The extent of each complex depends on chloride concentration, temperature, age, and pH of the solution. The complex undergoes hydrolysis (pH>3) as follows [5,6]:

\[
[RhCl_{6-n}(H_2O)_n]^{3-} + nH_2O \rightarrow [RhCl_{6-n}(H_2O)_n]^{3+} + nCl^{-}
\] (5)

Recovery of palladium, platinum, and rhodium metals have been performed by several separation methods: solvent extraction, ion exchange, non-aqueous methods, chelating resins, cementation by sacrificial metals [8] electrochemical method [9] and microbial method [3]. Among these techniques, the microbial method would be closest to microbial fuel cell technique. In this method Pd (II) reduction with formate as the electron donor in the presence of Gram-negative bacteria has been investigated. The advantages of the cementation process include its relative simplicity, ease of control and its ability to recover valuable metals [10,11]. However, the consumption of sacrificial metals and the redox potentials of sacrificial metals limit the application of this process [12]. Bio-sorption represents a biotechnological innovation as well as a cost-effective and excellent tool for recovery of precious metals from aqueous solutions [13]. This is due to the fact that the properties of certain types of inactive or dead microbial biomass materials allow them to bind and concentrate metal ions from industrial effluents and aqueous solutions [14].

Comparing the recovery techniques mentioned above, MFC can recover PGMs from its cathode chamber separated from the anode chamber containing anaerobic bacteria and organic electron donors, in addition to producing electric energy as a byproduct. Therefore, MFC would be a potentially advantageous technique in recovering PGMs from wastewaters coupled with electric power generation. It could be a potentially advantageous technique in recovering PGMs from wastewaters coupled with electric power generation. Therefore, the goal of this study is to verify the feasibility of recovering the PGMs from the cathode chambers simultaneously generating electrical power. PGM’s include Pd(II), Pt(IV), or Rh(III) containing artificial wastewaters as an electron acceptor of MFC. The effects of factors, such as initial Pd(II), Pt(IV), and Rh(III) concentrations, and reaction time on remaining concentration and recovery efficiency, were also evaluated and compared. The surface morphology and composition of elements were analyzed.

**Experimental section**

**Materials and instruments**

Cation exchange membrane (CEM, CMI-7000) was purchased from Membrane International, Inc. (New Jersey, USA). Carbon fiber (PANEX®) was purchased from Zoltex (Missouri, USA). Carbon cloth with a gas diffusion layer (type WLS1005) was purchased from CeTech Co. Ltd. (Taichung, Taiwan). Anaerobic sludge was obtained from an Okcheon wastewater treatment plant in Okcheon, Republic of Korea to inoculate anaerobic bacteria. CH₃COONa, NH₄Cl, KH₂PO₄, K₂HPO₄, NaCl, a solution (1000 ppm Pd(II)) of [PdCl₄]²⁻ in HCl, H₂PtCl₆·xH₂O, and RhCl₃·3.5H₂O were purchased from Sigma-Aldrich (Republic of Korea). Bacto yeast extract was purchased from DIFCO Laboratories (New Jersey, USA). LabVIEW system (National Instruments Model, NI-cDAQ NI 9129, Texas, USA), inductively coupled plasma-atomic emission spectroscopy (ICP-AES) (ICP-9000, Shimadzu, Kyoto, Japan), energy dispersive spectroscopy (EDS) (Quantax 200, Bruke, Seoul, Republic of Korea), scanning electron microscopy (SEM) (XL-30S FEG, Philips, Amsterdam, Netherlands), and pH-410 meter (Thermo Orion, Massachusetts, USA) were applied.

**MFC configuration**

A cubical dual-chambered MFC, home-made from acrylic, was used in this study, of which the chambers (length: 6.5 cm, width: 6 cm, height: 6 cm) was of an effective volume of 224 mL. Carbon brush was used as an anode (length 2.5 cm, outer diameter 2.5 cm) in the anode chamber, which was prepared by twisting carbon fibers as reported in literature [18,19]; and carbon cloth, with gas diffusion layers, was used as a cathode (surface area of 2.2 cm²; 1.7 × 1.3 cm) in the cathode chamber. The back surface of the cathode was connected to titanium wire with silver paste (Elcoat, Type P-100, Cans, Seoul, Republic of Korea) and was covered with nonconductive epoxy to expose only one side of electrode to the catholyte. Before connecting the titanium wire, the carbon cloth was pretreated as previously demonstrated [20]. Both these anode and cathode chambers were physically separated by a cation exchange membrane with an effective surface area of 36 cm² (6 cm × 6 cm) with bolts and nuts.

**MFC start-up and operation**

A mixture of 112 mL sludge and 112 mL artificial water (AW) was pumped into the anode chamber of MFC and then purified thoroughly with pure nitrogen gas for about 20 minutes prior to conducting experiments. The AW (pH = 7) contained the following: 1 g/L (1.22 mM) CH₃COONa as electron donors, 100 mM PBS buffer (mixture of 1.05 g/L KH₂PO₄ and 2.2 g/L K₂HPO₄) and 2.2 g/L Bacto yeast extract. The Bacto yeast extract is the water-soluble portion of autolyzed yeast, and it is a source of naturally occurring B-complex vitamins and other growth-promoting substances, making this product an excellent complement for a large variety of microorganisms. Two MFCs were prepared to confirm repeatability of the experiments. (1) When growing biofilms on the bio-anodes in MFCs, the anolyte was pumped into the anode chambers in a batch mode. And 100 mM PBS...
buffer (mixture of 1.05 g/L KH$_2$PO$_4$ and 2.2 g/L K$_2$HPO$_4$) was used as a catholyte in the cathode chambers, and continuously purged with air to utilize the dissolved oxygen as an electron acceptor [21]. For each fed-batch cycle, as the voltage drops below 50 mV, fresh AW was supplied to the anode chamber. After 3 repeatable stable voltages were obtained by continuously bubbling air into the cathode chamber, the MFC was assumed to have started successfully. The biofilm was coated on the brush anode, which functioned as a bio-anode, while the oxygen in the air was utilized as electron acceptors in the cathode chamber. 

The above-mentioned anolyte conditions for anode were kept constant throughout this study to obtain the constant anode voltage, when the PGM recovery operation was conducted. The supply of organic electron donor through the anode chamber was kept constant for the polarization and discharge experiments by continuously passing the donor solution from the reservoir containing 4 L solution with a peristaltic pump at a flow rate of 10 mL/min (hydraulic retention time (HRT) = 22.5 min). The catholyte was pumped into the cathode chamber in a batch mode to analyze the cathode parameters of MFC. When the two MFCs functioned steadily to give stable power, the cathode chamber of each MFCs was replaced by diluted [PdCl$_4$]$_2^-$, [PtCl$_6$]$_2^-$ or [RhCl$_6$-(H$_2$O)$_n$]$_{n-3}^-$ as an electron acceptor in a fed-batch mode with purging N$_2$ (10 mL/min) and continuously stirring magnetic bar to ensure thorough mixing and also eliminating the direct electron consumption effect by dissolved oxygen. (3) The [PdCl$_4$]$_2^-$ solution was prepared diluting the solution of [PdCl$_4$]$_2^-$ in HCl commercially purchased. [PtCl$_6$]$_2^-$ and [RhCl$_6$-(H$_2$O)$_n$]$_{n-3}^-$ solutions were respectively prepared by dissolving H$_2$PtCl$_6$∙xH$_2$O and RhCl$_3$∙3H$_2$O (II) chloride, respectively, with distilled water. These solutions were formed to stock solutions of 1000 ppm Pd$^{2+}$, Pt$^{4+}$ and Rh$^{3+}$ each, which were used as electron acceptors. Then, the solutions were further diluted to desired concentrations of interest with distilled water. A 0.2 or 1.0 M KCl (based on experimental condition) solution was added to the catholyte to support the ionic conductivity of the solution, and the pH was adjusted to 2 with diluted HCl and KOH solutions.

Calculation and analysis

MFC performance and electrochemical properties were measured with a LabView system. The voltage between the external resistance was measured by changing the resistance at a rate of 0.5 kΩ from 0 to 100 kΩ to 0.01 kΩ during the polarization test. The stable voltage was collected after about 2 minutes. Power density was calculated, as previously reported [22]. Based on the voltage measurements with different resistors, the voltage vs. current density (V-J) curves of MFCs were portrayed by obtaining voltage (V) and current density (J=V/RA).

Calculation and analysis

The morphologies and atomic compositions of the metal solids on the cathode surface were identified with a scanning electron microscopy (SEM) and energy dispersive x-ray spectrometer (EDS). SEM scans a beam of electrons over a specimen to produce a magnified image of an object. Electrons from the beam hit the surface of the object and bounce off it. A detector registers these scattered electrons and turns them into a picture. EDS systems are typically integrated into a SEM instrument. A typical EDS spectrum is portrayed as a plot of x-ray count rates (counts per second; cps) vs. energy (in keV). Energy peaks correspond to the various elements in the sample. EDS systems include a sensitive x-ray detector, a liquid nitrogen dewar for cooling, and software to collect and analyze energy spectra. To make it clear whether the metals were removed from the cathode to the surface of the cathode electrode by reduction and not just translocated to the anolyte, the SEM and EDS of PGM on the cathode were analyzed. [PdCl$_4$]$_2^-$, [PtCl$_6$]$_2^-$ and [RhCl$_6$-(H$_2$O)$_n$]$_{n-3}^-$ cannot be translocated to the anolyte because they are not ion-exchanged by cationic exchange membrane used as a separator. Therefore, Eq. (9) represents a removal efficiency of PGM.

Results and discussion

Effects PGM concentrations on the performances of the PGM-MFC

To characterize the electrochemical properties of the MFC using platinum group metal (PGM) ions as electron acceptors, the working voltage vs. current density (V-J) curves of MFCs for different initial concentrations of [PdCl$_4$]$_2^-$, [PtCl$_6$]$_2^-$, and [RhCl$_6$-(H$_2$O)$_n$]$_{n-3}^-$ in the catholytes were obtained. The electrochemical parameters are presented in table 1. 0.2 M KCl or 0.2 M NaCl was added to the catholyte to increase the solution conductivity, but 1 M KCl was added to the [RhCl$_6$-(H$_2$O)$_n$]$_{n-3}^-$ electron acceptor solution to keep [RhCl$_6$-(H$_2$O)$_n$]$_{n-3}^-$ in the soluble range. The curves were obtained by changing the external resistance...
from 100 kΩ to 0.01 kΩ, while the working voltage was measured between the resistor. Onset voltage (Vₜₐₓ) is defined as the voltage at zero current of the cell, and F.F. as Jₚₑᵃكسب/Am as well as Pₚₑᵃكسب using Jₚₑᵃكسب close to Jₚₑ as well as Pₚₑᵃكسب as determined by the slope of rising part of the voltage vs. current, decreased from 850 Ω to 70 Ω, as the cell was increased from 50 ppm to 1000 ppm. Interestingly, the repeated polarization curves for 500 ppm and 1000 ppm show improvements in all parameters except F.F. with an increase in the concentration, when compared to the initial curves (Table 1). Internal resistance, Rₑ, determined by the slope of rising portion of the voltage vs. current, decreased from 850 Ω to 70 Ω, as the cell was increased from 50 ppm to 1000 ppm. This represents that the Ohmic resistance decreased in the bulk of the electrolyte when [PdCl₄]²⁻ concentration was increased. Increasing [PdCl₄]²⁻ concentration could also reduce charge transfer resistance (Rₜₕₕ), expressed by Rₑ = nF/RT/iₚₑ, where n is overpotential. i₀ and iₚₑ are current and current density.

Interestingly, the maximum power point (Pₚₑᵃكسب) shifted towards the higher current density with an increase in PdCl₂ concentration as [PdCl₄]²⁻ (Figure 1A). When the initial curves are considered, almost all parameters improved significantly with an increase in the [PdCl₄]²⁻ concentration (Table 1), even if the onset potential (Vₜₐₓ) was increased from 50 ppm to 200 ppm, and then decreased from 200 ppm to 1000 ppm. Interestingly, the repeated polarization curves for 500 ppm and 1000 ppm show improvements in all parameters except F.F. with an increase in the concentration, when compared to the initial curves (Table 1). Internal resistance, Rₑ, determined by the slope of rising portion of the voltage vs. current, decreased from 850 Ω to 70 Ω, as the cell was increased from 50 ppm to 1000 ppm. This represents that the Ohmic resistance decreased in the bulk of the electrolyte when [PdCl₄]²⁻ concentration was increased. Increasing [PdCl₄]²⁻ concentration could also reduce charge transfer resistance (Rₜₕₕ), expressed by Rₑ = nF/RT/iₚₑ, where n is overpotential. i₀ and iₚₑ are current and current density.

### Table 1. Electrochemical parameters of MFC in different initial concentration solutions

| 500               | 0.594  | 6.08      | 0.401          | 6.08            | 2.44             | 115    | 0.675 |             |             |

Vₜₐₓ = Vₗ₋ relieveVₚₑᵃكسب, where Vₜₐₓ and Vₚₑᵃ обслужива potential, respectively. Vₜₐₓ is measured to be -0.281 V and kept constant by supplying the anode chamber with a continuous carbonaceous material (HRT = 22.5 min). Because the focusing electrode is cathode recovering PGMs, the anode is assumed not to vary during the operation of the MFC. Vₜₐₓ is obtained from Table 1, Vₜₐₓ = -0.281 V. For example, if Vₜₐₓ is 0.773 V for 500 ppm Pd²⁺, Vₜₐₓ is 0.773 V – 0.281 V = 0.492 V. The theoretical cathode potential can be calculated for 500 ppm Pd²⁺ and [Cl⁻] = 0.2 M using the Nernst equation at 25°C. Vₗ₋ relieve = 0.59 V – (RT/2F)ln([Cl⁻]/[PdCl₄]²⁻) = 0.59 V – (0.0592 V/2)log[(0.2) ⁴ /4.70x10⁻³] = 0.604 V. Therefore, the measured Vₜₐₓ is 0.112 V lower than the theoretical value. For the same concentration of [PdCl₄]²⁻, the theoretical cathode potential is calculated to be Vₗ₋ relieve = 1.011 V – (RT/2F)ln([Cl⁻]/[PdCl₄]²⁻) = 1.011 V – (0.0592 V/2)log(0.04/0.00256) = 0.976 V. For 500 ppm PdCl₂, the theoretical cathode potential is calculated to be Vₗ₋ relieve = 0.431 V – (RT/3F)ln([Rh³⁺]/[Rh₂²⁺]) = 0.431 V – (0.0592 V/3)log(1/0.00480) = 0.385 V. The observed cathode potential of Rh₃⁺ is 0.594 V – 0.281 V or 0.313 V, which is 0.072 V lower than theoretical value. Generally, the observed cathode potential is lower than the theoretical value due to the overvoltage.

The highest Pₚₑᵃكسب was found to be 7.03 W/m² with a F.F. of 0.638 at 1000 ppm (9.40 mM) of PdCl₂, as shown in Table 1, which is the test solution with the highest concentration in this study. At this power density, the resulting maximum voltage (Vₚₑᵃكسب), maximum current density (Jₚₑᵃكسب), and internal resistance were 0.556 V, 12.64 A/m², and 70 Ω, respectively (Table 1). Under the same concentration (100 ppm [PdCl₄]²⁻) and the same anolyte condition, the Pₚₑᵃكسب (1.30 W/m² as shown in table 1) obtained from this study was 3 times higher than the reported value (0.433 W/m²) for Hg²⁺ at pH 2.0.¹⁹ The Pₚₑᵃكسب (7.03 W/m²) with 1000 ppm PdCl₂ from this study is 1.63 times higher than the Pₚₑᵃكسب (4.3 W/m²) produced for MFC of which the catholyte was a 50 mM K₂Fe(CN)₆ solution in 100 mM KH₂PO₄ (adjusted to pH 7 with 1 N NaOH) [24]. Power production in cube air-cathode MFC containing...
Figure 1. Power vs. Current density (P-J) curves of MFC with different initial concentrations; (A) 50 ~ 1000 ppm Pd$^{2+}$ as [Pd(II)Cl$_4$]$^{2-}$ with 0.2 M NaCl at pH 2, (B) 100 ~ 500 ppm Pt$^{4+}$ as [Pt(IV)Cl$_6$]$^{2-}$ with 0.2 M NaCl at pH 2, and (C) 50 ~ 500 ppm Rh$^{3+}$ as [Rh(III)Cl$_6$(H$_2$O)$_n$]$^{3-}$ with 1.0 M KCl at pH 2.0. a: 50 ppm; b: 100 ppm; c: 200 ppm; d: 500 ppm. Data were measured in duplicate.

As a result, the magnitude of $P_{\text{max}}$ for 500 ppm was in the order of [PtCl$_6$]$^{2-}$ (5.04 W/m$^2$) > [PdCl$_4$]$^{2-}$ (4.22 W/m$^2$) > [RhCl$_6-n$(H$_2$O)$_n$]$^{3-}$ (2.44 W/m$^2$) (Table 1). $I_{\text{max}}$ is in the same order as $P_{\text{max}}$ (15.42 A/m$^2$ for [PtCl$_6$]$^{2-}$, 8.00 A/m$^2$ for [PdCl$_4$]$^{2-}$, and 6.08 A/m$^2$ for [RhCl$_6-n$(H$_2$O)$_n$]$^{3-}$). However, $V_{\text{max}}$ was in the order of [PtCl$_6$]$^{2-}$ (0.528 V) > [RhCl$_6-n$(H$_2$O)$_n$]$^{3-}$ (0.401 V) > [PtCl$_6$]$^{2-}$ (0.333 V). $R_{\text{int}}$ was in the order of [RhCl$_6-n$(H$_2$O)$_n$]$^{3-}$ (115 $\Omega$) > [PdCl$_4$]$^{2-}$ (130 $\Omega$) > [PtCl$_6$]$^{2-}$ (138 $\Omega$). F.F. is in the order of [RhCl$_6-n$(H$_2$O)$_n$]$^{3-}$ (0.675) > [PtCl$_6$]$^{2-}$ (0.64) > [PdCl$_4$]$^{2-}$ (0.601) (Table 1).

According to Table 1, the $V_0$ of Pt$^{4+}$ was changed to a higher potential side as the Pt$^{4+}$ ion concentration increased, while those of Pd$^{2+}$ and Rh$^{3+}$ were pinned at the constant values. Deposited Pt can work as a catalyst for reduction of protons and incur no onset pinning. A repeated curve of Pd$^{2+}$ showed higher current density than the initial curve (Table 1). Also, the second polarization curve after the initial polarization experiments showed an increase in current density due to exposure of the catalytic surface deposited with Pd to the solution (Table 1). Again, it is found that this new surface does not only catalyze H$^+$ reduction, but also Pd$^{2+}$ reduction. At a high Pd$^{2+}$ concentration, most of the reduction reaction seems to occur from Pd$^{2+}$, although hydrogen evolution reaction also increases significantly in the low working voltage region of MFC. In order to achieve high rates of Pd recovery, a low pH range is undesirable due to Eq. 11, because the $\sigma$ becomes low due to the side reaction by proton reduction.

$$\eta = \sigma Q,$$

where $\eta$ = efficiency, $\sigma$ = fraction of main recovery, and $Q$ = total charge passed.

When the anode reaction is fast enough not to affect the full cell reaction, the limiting current density ($I_L$) in the V-J curve increased with respect to an increase of PGM ion concentration, and is represented by Eq. (12), where it is proportional to the bulk concentration ($C_{\text{bulk}}$) of the PGM ions in the solution over the $I_L$ region.

$$I_L = nFDC_{\text{bulk}}/\delta,$$

where $D$ is the diffusion coefficient of PGM ions, $C_{\text{bulk}}$ is the bulk concentration, $\delta$ is the thickness of diffusion layer, $n$ is number of electrons transferred, and $F$ is Faraday constant. If one draws a relationship of $I_L$ vs. PGM ion bulk concentration, $I_L$ is clearly observed to increase proportionally with an increase in PGM ion concentration by mass transfer of reducible species. This means that the $I_L$ is solely affected by the diffusion control on the cathode. A concentration change of [PtCl$_6$]$^{2-}$ from 100 ppm to 500 ppm incited large $V_0$ shifts from 0.895 V to 0.385 V, compared to the equilibrium cell voltage $E_{\text{eq}}$, if $E_{\text{eq}}$ is assumed to be 1.316 V (Table 1). The $V_0$ shift rate (681 mV/decade) is 31 times higher than expected from a Nernstian behavior (15 mV/decade) from 100 ppm [PtCl$_6$]$^{2-}$ to 500 ppm [PtCl$_6$]$^{2-}$ presumably because there is a catalytic effect due to a metal deposit. $V_0$s of [PdCl$_4$]$^{2-}$ and [RhCl$_6-n$(H$_2$O)$_n$]$^{3-}$ did not show such a shift (Table 1).
Usually the Pt deposit reaction from \([\text{PtCl}_6]^{2-}\) solution occurs through a two-step reaction, as shown in Eq. (1) and (2) (\(E^{\text{red}}_{\text{PtCl}_6} = 1.131 \text{ V from Eq. (2) and (3)}, \text{and } E^{\text{red}}_{\text{PtCl}_6} = 1.295 \text{ V from Eq. (2) and (4)},\)) which could be deciphered from the literature \([26,27]\). However, such processes in this study were not distinguishable and resulted in a merging of two processes. The catalytic effects of Pt deposit (at the onset potential) make the shapes of power curves of \([\text{PtCl}_6]^{2-}\) and \(V_p\) dissimilar from other two kinds of reactions, such as \([\text{PdCl}_4]^{2-}\) and \([\text{RhCl}_6]^{3-} (\text{H}_2\text{O})_n\) (Figure 1, Table 1). An aged electrode of Pd-MFC actually showed significant improvements in the electrochemical parameters, as shown in Table 1. The \(V_p\) pinning phenomena of \([\text{RhCl}_6]^{3-} (\text{H}_2\text{O})_n\) were similar to Pd-MFC (Table 1).

Knowledge of the amount by which the working voltage of a cell delivers a particular level of the current deviating from its equilibrium value, \(E^{\text{eq}}\), is of central importance in assessing the performance of a practical battery system \([28]\). This working voltage can be associated with \(R_{\text{ct}}\) and overvoltage, as discussed in the introduction. Solely correlating the \(P_{\text{max}}\) improvement of the cell with the lowered Ohmic resistance could be misleading because it is increased not only by lowering \(R_{\text{ct}}\) as Ohmic resistance, but also by lowering the charge transfer resistance inversely related to PGM ion concentration. The electrochemical parameters should also be compared between the MFCs, such as onset voltage \(V_o\), peak current density \(I_{\text{pmax}}\), maximum voltage \(V_{\text{max}}\) at the \(P_{\text{max}}\), maximum current density \(I_{\text{pmax}}\) at the \(P_{\text{max}}\), fill factor (F.F.), and internal resistance \(R_n\) including charge transfer resistance, as criteria for judging the cell performance.

**Discharge curves of the MFC with different initial concentrations of PGM**

To characterize the discharging behavior of the MFC, the working voltage vs. time in relation to Pd\(^{2+}\) concentration with 1000 \(\Omega\) load resistor was recorded with different Pd\(^{2+}\) concentrations (Figure 2A). When the anode chamber conditions remained unchanged, the cathode chamber contained different initial Pd\(^{2+}\) concentrations from 50 ppm to 500 ppm using 0.2 M KCl as a supporting electrolyte. Through the anode chamber, the electron donor solution was passed continuously, so that the dissolution of the fed-batch catholyte could represent the discharge of the MFC. The discharge voltage increased initially as the concentration of Pd\(^{2+}\) was increased; the voltage changed from 0.51 V to 0.70 V when the initial concentration of Pd\(^{2+}\) increased from 50 ppm to 500 ppm. At 50 ppm, the discharge voltage dropped to a very low level within 1 hour; but from 100 ppm to 200 ppm, the voltage plateaued for a progressively longer time with a progressive increase in Pd\(^{2+}\) concentration; then the voltage rapidly dropped again. At 500 ppm, the voltage retained a plateau region up to 40 hours, and then finally started to drop slowly. In the fed-batch catholyte system with an initial concentration of 500 ppm, the discharging showed electrical energy production rate approximately higher than 39.2 Wh/Kg(Pd) as a byproduct along with Pd metal recovery. In reality, the concentration range from 50 ppm to 500 ppm tested could exist because the Pd\(^{2+}\) concentration of the spent solution disposed from the manufacturing of glass fiber catalysts for purification of automobile exhaust gasses is as high as 1000 ppm, as mentioned in the introduction. The difference between this study and the bacterial reduction reported in the literature \([3]\) shows that the former can produce electrical energy while recovering Pd metals on the cathode in a separate chamber, but the latter can only recover Pd metals associated with the bio-cells in the same container with organic material located. The MFC method allows for a clean Pd metal recovery, as well as electric power generation.

Figure 2B shows the discharging characteristics of the MFC with Pt\(^{4+}\) as \([\text{Pt(IV)Cl}_6]^{2-}\) electron acceptors in the cathode chamber with 0.2 M NaCl as a supporting electrolyte. The experimental conditions were the same as those for Pd\(^{2+}\). The initial discharging voltage increased as the concentration of Pt\(^{4+}\) was increased; it was changed from 0.4 V to 0.7 V with an increase of the initial concentration of Pt\(^{4+}\) from 50 ppm to 500 ppm. At 50 ppm, the discharging voltage dropped to a very low level within 1 hour; but from 100 ppm to 500 ppm, the voltage decreased monotonously with time. From 50 ppm to 100 ppm, the discharging voltage dropped to the minimum level within 40 hours, but from 200 ppm to 500 ppm, the level of voltage remained high even until 22 hours, but it dropped quicker after 22 hours. With the fed-batch system, having an initial concentration of 500 ppm, discharge curves showed an electric energy production rate greater than about 17.2 Wh/kg(Pt) as a byproduct. This rate is lower than that of Pd-MFC.

Figure 2C shows discharging curves of Rh-MFC with Rh\(^{3+}\) as \([\text{Rh(III)Cl}_6]^{3-} (\text{H}_2\text{O})_n\) electron acceptors. As the Rh\(^{3+}\) concentration increases from 50 ppm to 200 ppm, the discharging voltage becomes higher. At an initial concentration of 50 ppm, discharging voltage dropped quickly, but from 100 ppm to 200 ppm it was slowly decreased. With the fed-batch system having an initial concentration of 200 ppm, the electrical energy production rate was greater than about 35.1 Wh/kg(Rh) as a byproduct. Discharging time lasted 40 hours for all concentrations tested.

Coulombic efficiency (CE\%) could be calculated according to Eq. (10) with a sample. It was found to be about 49.6% for 500 ppm.
concentration of Pd $^{2+}$ in the solution at the end of operational cycle was 99.6%, 99.7%, and 99.2% for initial concentrations of 50 ppm, 100 ppm, and 200 ppm, respectively. The RC data were measured in duplicate.

Effects of initial PGM concentrations on PGM remaining concentrations (RC) and recovery efficiency (RE).

To study the effects of initial Pd$^{2+}$ concentration on RC and RE, MFC reaction time is increased. The concentration of Pd$^{2+}$ was increased from 50 ppm to 200 ppm (Figure 3A). The RC data were monitored by ICP-AES, and the RE was calculated with the equation given in Eq. (9). Fig. 3A shows that the RCs increased correspondingly with time from 50 ppm to 100 ppm. However, at 200 ppm, the RE increased slightly slower with time. The results showed high RCs; 99.6%, 99.7%, and 99.2% for initial concentrations of 50 ppm, 100 ppm, and 200 ppm, respectively, after 40 hours reaction. The remaining concentration of Pd$^{2+}$ in the solution at the end of operational cycle slightly increased from 50 ppm to 200 ppm; 0.21 ± 0.01 ppm, 2.65 ± 0.00 ppm, and 1.68 ± 0.05 ppm for the same initial concentrations after 40 hours reaction time (Figure 3A). These RC and RE results represent that the MFC could remove Pd$^{2+}$ efficiently, and further it could be accelerated by increasing the surface areas of anode and cathode. When the MFC operates, the anionic movement into the anode chamber would be inhibited, but cationic movement into the cathode chamber would occur ideally due to the installation of cationic membrane as a separator. Therefore, the cationic species could accumulate into the cathode chamber from the anode chamber by migration of cations as well as diffusion. The cationic species will be mostly K$^+$, H$^+$, NH$_4^+$, and Na$^+$ ions, which are known as the composition of the anolyte in this study. Because only K$^+$, H$^+$, and [PdCl$_4$]$^{2-}$ exist in the cathode chamber of the MFC, the cationic species cannot be adsorbing or precipitating species with [PdCl$_4$]$^{2-}$ or Pd metals. The [PdCl$_4$]$^{2-}$ consumption from the catholyte occurs only by way of reduction at the cathode. The quality Pd metal was obtained, and this will be discussed with SEM and EDS later on. Therefore, the calculation of REs performed using ICP-AES data, as given in Eq. (9), would be realistic. The MFC method was very promising for Pd recovery because of high recovery efficiency.

The concentration of Pt$^{4+}$ as [Pt(IV)Cl$_6$]$^{2-}$ was changed from 50 ppm to 200 ppm to study the concentration effects of Pt$^{4+}$ on its recovery efficiency with time. The trend was similar to the Pd$^{2+}$ remaining concentration and Pd recovery efficiency. Figure 3B shows that within 40 hours, the REs of Pt reached 99.9%, 99.5%, and 99.5% for the initial concentrations of 50 ppm, 100 ppm, and 200 ppm, respectively. The results generally represented a high recovery efficiency. The negative level of Pt$^{4+}$ in the solution containing medium high initial concentration of Pt$^{4+}$ was also a little higher than in low initial concentrations in the 40-hour time interval-RCs at the initial concentrations of 50 ppm, 100 ppm, and 200 ppm were 0.10 ± 0.0 ppm, 1.23 ± 0.25 ppm, and 4.30 ± 0.61 ppm, respectively (Figure 3B). The initial Rh$^{3+}$ as [Rh(III)Cl$_6$]$_{2-}$ concentration was also varied from 50 ppm to 200 ppm to evaluate the effect of initial Rh$^{3+}$ on Rh recovery efficiency (RE) and remaining concentration (RC) of Rh$^{3+}$ for about 40 hours (Figure 3C). The trend was similar to the RCs of Pd$^{2+}$ and Pt$^{4+}$ and REs of Pd and Pt. As Rh$^{3+}$ concentration was increased from 50 ppm to 100 ppm, the RE was increased from 97.8% to 99.2%. And with further increase to 200 ppm, the RE was slightly lowered to 98.7% in 40 h time interval. Additionally, RCs at the initial concentrations of 50 ppm, 100 ppm, and 200 ppm were 1.10 ± 0.02 ppm, 0.76 ± 0.02 ppm, and 2.54 ± 0.03 ppm, respectively. In conclusion, the MFC recovery systems could be utilized to recover PGMs because all PGMs were recovered at a high recovery efficiency (RE).

Surface analysis of cathodes deposited with PGMs

SEM micrographs of palladium (Pd), platinum (Pt), and rhodium (Rh) metals deposited on carbon cloths of the same area were given in Figure 4, where Pd, Pt, and Rh metal deposition time was 30 hours in 200 ppm solution. Typical Pd deposits were of compact crystalline and continuous spots. Rh deposits were of smaller round-like layered shapes than the Pd deposits (Figure 4A and Figure 4C), while Pt deposits were of powdery particles (Figure 4B). "a" represents a SEM micrograph of the plain carbon cloth without any deposit with a magnification of 1000x. It is known that the deposit current is an expression of reaction rate through Faraday’s Law in an electrochemical reaction, and the morphologies of metal deposits would be influenced by the nucleation and growth rate of metal deposit. The surface morphology of Rh deposits was of smaller particles than Pd particles because its deposition current was lower than that of Pd deposition; Rh deposition also showed a lower power density production partially caused by the lower current, compared with Pd or Pt production. EDS analysis

![Figure 3](image-url)
Figure 4. Scanning electron microscopy (SEM) micrographs of carbon cloth with deposition of Pd (A), Pt (B) and Rh (C) metals. Here “a” corresponds to the plain carbon cloth electrode surface with a magnification of 10000x for control, and b, c, and d correspond to Pd, Pt and Rh metal depositions on the electrodes for 30 hours in 200 ppm concentration solution with magnifications of 10000x, 1000x and 100x, respectively.

Figure 5. Energy dispersive X-ray (EDS) data of (A) Pd, (B) Pt, and (C) Rh metals deposited on carbon cloth electrodes under 10.0 kV, compared with the fresh carbon cloth cathode (D). The metals were deposited in the same concentration solution of 200 ppm for the same reaction time of 30 hours.
showed typical specific peaks for Pd, Pt, and Rh (Figure 5). Especially Pd, Pt, and Rh showed very strong peaks at energy levels of 2.9 keV, 2.2 keV, and 2.7 keV, clearly indicating metals were the main elements in the deposits, while there was no peak for the plain carbon cloth in this range (Figure 5D), showing that pure metal deposits were formed on the carbon cloth surface. However, Pt peak was weaker than Pd and Rh peaks, even though the peak showed a specific peak at an energy level of 2.2 keV. The reason for why the peak intensity is relatively weaker for EDX of Pt is not known.

Conclusions

Based on the finding of this study, the two-chamber MFC system could be successfully applied to the recovery of PGMs from artificial wastewaters containing Pd\(^{2+}\), Pt\(^{4+}\), or Rh\(^{3+}\) with electrical power generated simultaneously. The power generated was found to be increased with an increase in PGM concentration. And with 1000 ppm initial Pd\(^{2+}\) concentration, the highest \(P_{\max}\) of 7.03 W/m\(^2\) with a fill factor of 0.638 was achieved from this study. The electrical energy generation rate was in the order of Pd-MFC (39.2 Wh/kg) > Rh-MFC (35.1 Wh/kg) > Pt-MFC (17.2 Wh/kg). After 40 hours reaction, the removal efficiency range of 98.7% – 99.5% was achieved for all PGMs with initial concentrations ranging from 50 ppm to 200 ppm. In future, higher \(P_{\max}\) can be expected from a system optimized with a large-scale reactor design.
