(Dated: February 1, 2008)

A continuum theory is used to predict scaling laws for the morphological relaxation of crystal surfaces in two independent space dimensions. The goal is to unify previously disconnected experimental observations of decaying surface profiles. The continuum description is derived from the motion of interacting atomic steps. For isotropic diffusion of adatoms across each terrace, induced adatom fluxes transverse and parallel to step edges obey different laws, yielding a tensor mobility for the continuum surface flux. The partial differential equation (PDE) for the height profile expresses an interplay of step energetics and kinetics, and aspect ratio of surface topography that plausibly unifies observations of decaying bidirectional surface corrugations. The PDE reduces to known evolution equations for axisymmetric mounds and one-dimensional periodic corrugations.

Novel small devices rely on the stability of nanoscale surface features. The lifetimes of nanostructures decaying via surface diffusion scale as a large power of their size and increase with decreasing temperature. Below roughening, crystal surfaces evolve via the motion of atomic steps bounding nanoscale terraces [1] [2].

Experiments with decaying surface features [3] [4] [5] [6] [7] [8] [9] are useful for testing step models. Particularly informative are observations of bidirectional corrugations relaxing below roughening [5] [6] [7] [8] [9]. In lithography-based experiments [5], where initial wavelengths in two directions differ significantly and profiles depend nearly on one space dimension (1D), the surface height decays exponentially with time. By contrast, in sputter-rippling experiments [7] [8], where initial wavelength ratios are closer to unity and profiles evidently depend on two space dimensions (2D), height spatial-frequency components decay inverse linearly with time. These observations have previously evaded a unified theory [10] [11]. In this Letter, we use a continuum theory to plausibly unify these observations via an appropriate tensor mobility.

There are two main theoretical approaches to crystal surface morphological evolution below roughening. One approach follows the motion of steps in the spirit of the Burton-Cabrera-Frank (BCF) model [1] via numerical solutions of coupled equations for step positions [12] [13]. Step simulations in 1D [12] show exponential decay of surface corrugations with attachment-detachment limited (ADL) kinetics, in agreement with lithography experiments [5]. Step simulations in 2D invoke axisymmetry [13], and are thus limited in their ability to make predictions for general surface morphologies.

Another approach relies on equilibrium thermodynamics and mass conservation using continuum evolution laws [14] [15] [16] [17] [18] [19] [20] such as partial differential equations (PDEs). PDEs enable simple scaling predictions; see e.g. [17]. Continuum models are criticized [12] for their inaccurate description of macroscopic, planar surface regions (“facets”), but progress is made in including facets in evolution laws [21]. Continuum theories have not previously unified observations of decaying surface corrugations [11]. An ingredient of such theories is the scalar mobility for the adatom flux in 2D [10] [17] [19] [20], which does not essentially distinguish adatom fluxes parallel to steps from fluxes transverse to steps. This formulation is valid when steps are everywhere parallel [17], but is shown here to be inadequate in general cases.

In this Letter we plausibly unify experimental observations of decaying profiles by invoking a tensor macroscopic mobility for the adatom flux in a setting of isotropic terrace diffusion; see Eqs. (8)–(10). An elaboration derivation is given elsewhere [22]. Here, we provide a more general yet simpler derivation. We show that the resulting PDE for the height profile reduces to known evolution laws for 1D gratings and 2D nanostructures. Further, we relate scaling predictions of the general theory to relaxation experiments. We find that observed scaling laws with time can arise from competition of step kinetics with surface topography. This effect is due to coupling of adatom flux components via terrace diffusion, and is distinct from the influence of step edge diffusion, e.g. work in [24]. A similar effect of anisotropic terrace diffusion on step meandering is studied in [24]. By contrast to [24], our step model has scalar microscopic parameters.

First, we describe the model of step flow [1]. A top terrace is surrounded by non-self-intersecting and non-crossing steps numbered \( i = 1, 2, \ldots \); \( i = 1 \) denotes the top step. The projection of steps on the basal (high-symmetry) plane is described by the position vector \( \mathbf{r}(\eta, \sigma, t) \) where \( t \) is time; \( \eta = \eta_i \) at the \( i \)th step, \( \eta_i < \eta < \eta_{i+1} \) on the \( i \)th terrace, and \( \sigma \) gives the position along each step; see Fig. 1. The unit vectors normal and parallel to steps in the direction of increasing \( \eta \) and \( \sigma \) are \( \mathbf{e}_\eta \) and \( \mathbf{e}_\sigma \); \( \mathbf{e}_\eta \cdot \mathbf{e}_\sigma = 0 \). The metric coefficients (to be used below) are \( \xi_{\eta} = |\partial_\eta \mathbf{r}| \) and \( \xi_{\sigma} = |\partial_\sigma \mathbf{r}| \); \( \partial_\eta := \partial / \partial \eta \).

Mass conservation for atoms is described by

\[
\nu = \mathbf{e}_\eta \cdot \frac{d \mathbf{r}}{d t} \bigg|_{\eta=\eta_i} = \frac{\Omega}{a} \left[ J_{i+1}^{\perp}(\eta_i, \sigma, t) - J_i^{\perp}(\eta_i, \sigma, t) \right]; \quad (1)
\]
\[ U^{\text{int}} = g \left[ \Phi(\eta, \eta_{i+1}; \sigma) - \Phi(\eta, \eta_{i-1}; \sigma) \right], \]  

where \( g \) (energy/length) is positive, and \( \Phi(\eta, \xi; \sigma) \) is geometry-dependent, differentiable with \( (\eta, \xi) \) and satisfies \( \Phi(\eta, \eta_{i+1}) \delta \sigma_{i} = \Phi(\eta_{i+1}, \eta) \delta \sigma_{i+1} \). Equations \( \text{(1)} \) and \( \text{(1)} \) describe coupled step motion via adatom isotropic diffusion across terraces and atom attachment-detachment at steps. To enable predictions for decaying surface profiles at length scales large compared to the terrace width, \( \delta \eta_{i} \), we next derive a PDE for the continuum height profile, \( h(r, t) \). Thus, \( \delta \eta_{i} \) is small compared to: (i) the length over which the step density, \( \frac{a}{\delta \sigma} \), varies; and (ii) the step radius of curvature, \( 1/k \). We take \( \delta \eta_{i} = \eta_{i+1} - \eta_{i} \rightarrow 0 \) with fixed \( \frac{\sigma}{\delta \sigma_{i}} \). In this limit, \( \frac{a}{\delta \sigma} \rightarrow |\nabla h| \), where \( |\nabla h| = (\partial_{x} h, \partial_{y} h) \) and \( v_{i} \rightarrow \frac{\partial h}{\nabla h} \).

First, we note that the familiar continuum mass conservation statement for atoms comes from the step velocity law, Eq. \( \text{(1)} \). By using the continuum surface current \( J(r, t) \), the continuous extension of \( J_{i}(\eta_{i}, \sigma, t) \), we obtain

\[ \partial_{t} h = -\frac{\Omega}{\xi_{\sigma}} [\partial_{\eta}(\xi_{\sigma} J^{\eta}) + \partial_{\sigma}(\xi_{\sigma} J^{\sigma})] = -\nabla \cdot J. \]  

Next, we apply Eqs. \( \text{(2)} \) to relate \( J(r, t) \) to the continuum step chemical potential, \( \mu(r, t) = \mu(\eta_{i}, \sigma, t) \). The following procedure is more general than the analysis in \( \text{(2)} \). (i) We apply Eq. \( \text{(2)} \) with the upper sign for \( \sigma \), and with the lower sign for \( \sigma' = \sigma + \delta \sigma \). (ii) We expand the transverse current, \( J_{i}^{\eta} \), the density \( C_{i} \), and \( \mu_{i} \), each evaluated at \( (\eta_{i+1}, \sigma + \delta \sigma) \) at \( (\eta_{i}, \sigma) \) using \( J_{i} = -D_{s} \nabla C_{i} \), e.g., \( C_{i+1, \sigma + \delta \sigma} \approx C_{i+1} - D_{s} \left( \xi_{\sigma} \delta \sigma \xi_{\sigma} J_{i}^{\sigma} \right) \) where \( \xi_{\sigma} \) are constants and \( J_{i}^{\sigma} = J_{i} + \xi_{\sigma} \) is the longitudinal current. (iii) We subtract Eqs. \( \text{(2)} \) dropping terms that are negligible as \( \delta \eta_{i} \rightarrow 0 \). Thus, we find

\[ \frac{1 + q}{\delta \rho_{i}} J_{i}^{\eta} + \frac{D_{s} C_{i}}{k_{B} T} \frac{\delta \rho_{i}}{\xi_{\sigma}} \approx \frac{C_{i+1} D_{s}}{k_{B} T} \frac{\delta \rho_{i}}{\xi_{\sigma}} \]  

where \( q = \frac{2D_{s}}{k_{B} T} \). By setting \( \delta \sigma = 0 \) in Eq. \( \text{(6)} \) we obtain

\[ J_{i}^{\sigma} \rightarrow J(r, t) \cdot e_{\sigma} = -\frac{D_{s} C_{i}}{k_{B} T} \frac{1}{1 + q |\nabla h|} \frac{\partial \mu_{i}}{\xi_{\sigma}} \]  

where \( q(a/\delta \rho_{i}) \) is fixed. Hence, Eq. \( \text{(6)} \) reduces to

\[ J_{i}^{\sigma} \rightarrow J(r, t) \cdot e_{\sigma} = -\frac{D_{s} C_{i}}{k_{B} T} \frac{\partial_{\sigma} \mu}{\xi_{\sigma}}. \]  

By Eq. \( \text{(7)} \), the continuum longitudinal current, \( J_{s} \), has the terrace diffusivity, \( D_{s} \), whereas the normal current \( J^{n} \), Eq. \( \text{(7a)} \), has the slope-dependent effective diffusivity \( D_{s} = D_{s}(1 + q |\nabla h|)^{-1} \); \( D_{s} \) equals \( D_{s} \) for terrace-diffusion limited (TDL) kinetics, \( q |\nabla h| \ll 1 \). This behavior results from coarse-graining in 2D, combining atom
attachment-detachment, terrace diffusion and step topography. For ADL kinetics, $q/\nabla h > 1$, $J^0$ is sensitive to step variations of $\mu$ because steps are sources and sinks of atoms by Eqs. (2), whereas $J^\sigma$ is sensitive to space variations of $\mu$ along steps due to adatom diffusion between non-parallel steps. Equations (7) read $J = -C_3\mathbf{M} \cdot \nabla \mu$ where the mobility $\mathbf{M}$ ([length]/[energy/time]) is a second-rank tensor (a $2 \times 2$ matrix where $\mathbf{J}$ and $\nabla \mu$ are 2-column vectors). In the basal plane Cartesian system ($x, y$) the matrix elements $M_{ij}$ ($i, j = x, y$) of $\mathbf{M}$ are

$$M_{xx} = \frac{D_3}{k_B T} \left[ \frac{1}{1 + q/\nabla h} + \alpha^2 \right], \quad (8)$$

$$M_{xy} = M_{yx} = -\frac{D_3}{k_B T} \frac{q/\nabla h}{1 + q/\nabla h} \alpha, \quad (9)$$

$$M_{yy} = \frac{D_3}{k_B T} \left[ \frac{1}{1 + q/\nabla h} + 1 \right], \quad (10)$$

where $\alpha := \frac{\partial h}{\partial \nabla h}$. For biperiodic profiles, $\alpha$ is estimated by $\frac{\lambda_3}{\lambda_\nu}$, the (aspect) ratio of dominant (maximum-amplitude) wavelengths in $x$ and $y$; we take $\lambda_3 \leq \lambda_\nu$ and, thus, $\alpha \leq 1$.

Next, we obtain a PDE for the height profile, $h(r, t)$. First, we derive a relation of $\mu$ with $\nabla h$ via Eqs. (5) and (6) (i) We expand in $\Phi(\eta, \xi; \sigma)$ the function $\Phi(\eta, \xi; \sigma)$ of Eq. (7), where $\xi = \eta_{i+1}$ or $\eta_{i-1}$, (ii) We use an identity for $\Phi$, which stems from the definition of $U^{int}$ [22]. After some algebra, the limit $\delta \eta_i \rightarrow 0$ yields

$$\mu = \Omega [g_1 \kappa - g_3 \nabla \cdot (\nabla h \nabla h)], \quad (11)$$

where $\kappa = -\nabla \cdot \frac{\nabla h}{\nabla h}$ is the step edge curvature, $g_1 = \frac{2}{\nabla h}$ and $g_3 = \frac{3g_1}{\alpha^2} (\frac{\nabla h}{\nabla h})^2 \Phi(\eta, \eta); g_1$ and $g_3$ have dimensions energy per area. This $\mu$ also results from the variational derivative of the surface energy $E = \int \int dx dy |g_1| \nabla h + (g_1/3) |\nabla h|^3| [17, 22]. By Eqs. (5), (7) and (11),

$$\partial h = B \nabla \cdot \left\{ \mathbf{\Lambda} \nabla \left( \frac{\nabla h}{\nabla h} \right) + \frac{g_3}{g_1} \nabla \cdot (\nabla h \nabla h) \right\}, \quad (12)$$

where $\mathbf{\Lambda} = -\frac{k_B T}{\Omega} \mathbf{M}$ and $B = \frac{D_3 C_3}{k_B T} \alpha^2$ ([length]$^4$/time). By Eqs. (5), (10) for $\mathbf{M}$, Eq. (12) describes an interplay of step energetics and kinetics, and aspect ratio $\alpha$. This dependence on $\alpha$ is absent in previous studies of morphological evolution below roughening [10, 17, 19, 20].

It is tempting to compare Eq. (12) and its ingredients to similar continuum laws for steps, e.g. Eq. (14) of [24] for a step meander without deposition. The last term of Eq. (14) in [24] pertains to the flux along the step edge, with a mobility that depends on the step edge slope. In the small slope limit, this term appears to agree with Eq. (7b). We emphasize that the isotropic physics of our model is different from that of [24] where anisotropic terrace diffusion coexists with step edge diffusion.

We now show that Eq. (12) reduces properly to known macroscopic laws for everywhere parallel steps.

First, we have $J^\sigma = 0$ by which the effective mobility becomes $M = \frac{D_3}{k_B T} (1 + q/\nabla h)^{-1}$, a scalar. For straight steps (in 1D), $\eta = x$, we have $\kappa \equiv 0$ and the PDE becomes $\partial h = -B_3 \partial_x \left\{ (1 + q/\nabla h)^{-1} \partial_{xx} (\partial_x h \partial_x h) \right\}$ where $B_3 = \frac{D_3 C_3 q}{k_B T}$, which is consistent, for example, with [12]. The reduced PDE can be applied to systems of periodic corrugations in 1D [3, 12, 18]. For concentric circular, descending steps in 2D, $\eta \propto r$ (polar distance), we have $\kappa = 1/r$ and the PDE (12) becomes $\partial h = B r^{-1} \partial_r \left\{ (1 + q/r)^{-1} \right\}$, which is applied to decaying axisymmetric mounds [1, 13, 17, 24].

We now apply separation of variables to Eq. (12) for smooth regions, aiming to unify decay laws in relaxation experiments. Consistent with step simulations in 1D [12] and kinetic Monte Carlo simulations in 2D [19], both for initial sinusoidal profiles, we set $h(r, t) \approx A(t) H(r)$ and find $A(t)$. This variable separation, which we call a “scaling Ansatz”, is satisfied only approximately: additive terms in $\mu$ and $\mathbf{M}$ scale differently with $A$. In $\mu$, Eq. (11), the step line tension $(g_1)$ term scales with $A^0$ and the step interaction $(g_3)$ term scales with $A^2$; in $M_{ij}$, Eqs. (8)–(10), the kinetic term $\beta = (1 + q/\nabla h)^{-1}$ must be compared to the aspect ratio squared, $\alpha^2$; $(\nabla h)^2 \approx \nu$ is a typical slope.

Our analysis does not address the evaluation of $H(r)$, which solves a nonlinear PDE. Because boundary conditions for $H$ at facet edges require feedback from step simulations [21], a viable numerical scheme for $H$ is not possible at the moment. By [12, 19], the scaling Ansatz seems reasonable for long $t$ and initial sinusoidal profiles.

We now focus on ADL kinetics, $\beta \ll 1$, distinguishing four cases. In the first case: (i) step interactions dominate, $|g_3 \nabla \cdot (\nabla h \nabla h)| \gg |g_1 \kappa|$ or $\frac{g_3}{g_1} \gg \left( \frac{\lambda_3}{\lambda_\nu} \right)^2$ by dimensional analysis for sinusoidal profiles, where $\nu \approx \frac{h_{yw}}{\lambda_\nu^2}$ and $h_{yw}$ is the peak-to-valley height variation; and (ii) $\beta < \alpha^2$ so that longitudinal fluxes are considerable. Thus, $\mu$ scales with $A^2$, and the matrix elements of $\mathbf{\Lambda}$ are $\Lambda_{xx} \approx \frac{(\partial h)^2}{|\nabla h|^2}$, $\Lambda_{yy} \approx -\frac{(\partial h)^2}{|\nabla h|^2}$, and $\Lambda_{xy} = \Lambda_{yx} \approx \frac{(\partial h)(\partial h)}{|\nabla h|^2}$, which scale with $A^0$ as in TDL kinetics. We find $\mathbf{A} \approx -c B_3 A^2$, where the dot denotes time derivative. Hence, $A(t) = A_0 \left( 1 + c B_3 A_0 t \right)^{-1}; A_0 := A(0).$ (13)

The constant parameter $c$ ([length]$^{-4}$) depends on $H(r)$ and is thus affected by facet evolution. Equation (13) suggests that surface relaxation is inverse linear with time if the $(y)$-adatom flux in the direction of the longer wavelength ($\lambda_y$) is significant.

In the second case: (i) step interactions remain dominant, and (ii) $\beta > \alpha^2$, so that transverse fluxes prevail. Thus, we obtain $\mathbf{A} = -C B_3 A$, by which

$$A(t) = A_0 e^{-C B_3 t}, \quad (14)$$

where $C$ is affected by $H$. The remaining cases for ADL kinetics follow similarly. The results are summarized
in Table I. The square-root decay with time when line tension dominates and $\beta > \alpha^2$ is in agreement with [19].

| Step interaction | $\alpha^2 < \beta \ll 1$ | $\beta \ll \alpha^2 \ll 1$ |
|------------------|------------------------|------------------------|
| $A_0 e^{-t/t_{\phi}}$ | $A_0 (1 + cB_3 A t)^{-1}$ |
| Line tension     | $A_0 \sqrt{1 - t/t^*}$  | $A_0 (1 - t/t^*)^3$    |

Our predictions, based on Eq. [12] with ADL kinetics, can be extended to TDL kinetics. The mobility $M$ then reduces to $\frac{\pi}{4B_3}$; thus, we obtain $\alpha$ or $[14]$, regardless of $\alpha$, for step-interaction or line-tension dominated $\rho$.

Next, we compare our predictions with observations of Si(001) [5, 7] and Ag(110) [8] corrugations. In Si(001), with $\ell = 2D_{\phi}/k \gtrsim 1000$ nm [10] and terrace width $\Delta w \lesssim 10$ nm [5, 7, 10], $q[|\nabla h|] \approx \frac{\ell}{\Delta w} \gtrsim 100$ which suggests ADL kinetics. We find decay laws comparing (i) the kinetic factor $\beta$, and $\beta \approx \frac{\Delta w}{4} \lesssim 0.01$, with the aspect ratio squared, $\alpha^2 \approx \frac{\Delta w}{4} \lesssim 0.01$; (ii) the square of step interactions $\frac{\Delta w}{g_1}$, with $\frac{\Delta w}{g_1}$ in [5]. In [5], $\alpha \approx 10^{-3}$ and thus $\beta \gg \alpha^2$. Also, $\nu \approx 1/30$ and $\frac{\Delta w}{g_1} \gg 1$ [20], and thus $\frac{\Delta w}{g_1} \gg \frac{1}{\nu}$ [20].

Equation (14) follows, in agreement with the decay in [5]. In [7], $\alpha \approx 10^{-1}$, $\nu \approx 1/15$ and $\frac{\Delta w}{g_1} \approx 100$ [20]. So, $\beta \gg \alpha^2$ and $\frac{\Delta w}{g_1} > (\frac{1}{\nu})^2$. Equation (13) follows, in agreement with the inverse linear decay in [7].

We now discuss observations of Ag(110) [8] where step interactions are mainly entropic [2, 27]. By $\beta < 10^{-3}$ [8] and $\alpha \approx 1/15$ [28], we have $\beta < \alpha^2$. We estimate $\frac{\Delta w}{g_1} = \frac{\alpha}{a_0} - \frac{B_3}{a_0} \sinh \left( \frac{2\kappa T}{\alpha m_k} \right)^2 [2]$, and $\frac{\Delta w}{g_1} \approx \frac{\pi a_0 B_3}{m_k} \sinh \left( \frac{2\kappa T}{\alpha m_k} \right)^2 [2]$, where $\kappa$ is the kink formation energy, $0.04$ eV $\lesssim \kappa \lesssim 0.1$ eV [29]. $a$ is $1.4$ Å, $a_0 \approx 4$ Å, and $T = 210$ K; thus, $\frac{\Delta w}{g_1} \lesssim \frac{a_0}{a} \lesssim 1$. With $\nu \approx 2/25$ [8, 20], $\frac{\Delta w}{g_1} \approx O\left( \frac{\alpha^2}{\nu} \right)$; thus, our criterion for step energetics appears inconclusive for scaling. Possible reasons are deviations of initial profiles from sinusoidal ones and anisotropies in Ag(110), for which the model in [24] may be relevant. Although further study of the dynamics with reliable boundary conditions at facets is suggested, we view the condition $\beta < \alpha^2$ as an indicator of evolution toward inverse linear decay [8].

Our work forms a basis for a general approach to morphological evolution below roughening. Extensions in 2D include the ES barrier, long-range step interactions, and material deposition. Inclusion of the ES barrier [31] with rates $k_u$ and $k_d$ amounts effectively to $k = (1/k_u + 1/k_d)^{-1}$ in Eq. (12) [22]. Step-edge diffusion contributes to longitudinal fluxes but may not be important for Si(001), where ADL kinetics can dominate [2]. Anisotropic terrace diffusion, which is present in Si(001) and Ag(110), is not expected to alter the main decay laws presented here.

Connections of initial conditions and solutions for Eq. (12) to actual experimental decay laws have yet to be explored. Our scaling Ansatz should be tested for realistic initial profiles. Despite mode coupling [20] caused by the nonlinear PDE (12), our scaling should be valid for a range of prevailing wavelengths [7, 8, 20].

Other predictions of our approach include crossovers from exponential to inverse linear profile decay via aspect-ratio changes of the surface shape. Our work should stimulate further studies and relaxation experiments on surfaces below roughening.
