Biased Mixtures Of Experts: Enabling Computer Vision Inference Under Data Transfer Limitations

Alhabib Abbas and Yiannis Andreopoulos

Abstract—We propose a novel mixture-of-experts class to optimize computer vision models in accordance with data transfer limitations at test time. Our approach postulates that the minimum acceptable amount of data allowing for highly-accurate results can vary for different input space partitions. Therefore, we consider mixtures where experts require different amounts of data, and train a sparse gating function to divide the input space for each expert. By appropriate hyperparameter selection, our approach is able to bias mixtures of experts towards selecting specific experts over others. In this way, we show that the data transfer optimization between visual sensing and processing can be solved as a convex optimization problem. To demonstrate the relation between data availability and performance, we evaluate biased mixtures on a range of mainstream computer vision problems, namely: (i) single shot detection, (ii) image super resolution, and (iii) real-time video action classification. For all cases, and when experts constitute modified baselines to meet different limits on allowed data utility, biased mixtures significantly outperform previous work optimized to meet the same constraints on available data.

Index Terms—mixtures of experts, constrained data transfer, single shot object detection, single image super resolution, real-time action classification.

I. INTRODUCTION

When enough data is provided at test time, deep neural networks perform well for a wide range of challenging computer vision tasks. This is true especially for large models, as it is now well understood that the performance of neural networks scales with the number of trainable weights and the dimensionality of inputs processed during inference [19], [20]. However, the preconditions of data availability at test time is only possible when visual sensors and learned inference models coexist in hardware, which excludes cases where data is collected from sensors to be transferred and processed in remote environments. To bridge the gap between the input requirements of models that exist in such contexts, it is important to design models that can perform well when available communication resources are limited between the visual sensing and neural network processing parts of the system. For instance, cloud-based visual analysis, remote medical imaging, low-latency game streaming services, and drone or Internet-of-Things oriented computer vision [9], [29], [46], [55], have stringent constraints on the amount of data that can be provided between data-producing clients and data-consuming models on cloud servers. In order to bring computer vision models to wider practical use, it is therefore imperative to provide a solution to data availability constraints at test time.

Since deep learning models typically require a fixed amount of data for inference regardless of the specific nature of inputs to process, this leads to unnecessary and often unachievable demands in the amount of required data traffic for remote inference. Although some work has been devoted to input dimensionality reduction [18], [28], [50] and rate-constrained model optimization for specific tasks [21], [55], to the best of our knowledge, no task-agnostic method has been proposed that explicitly addresses data scarcity at test time by considering the variance between different domains in input space. The example of Figure 1 illustrates a classification task where the acceptable data cost of inference can vary for different input space partitions. That is, two features \( f_1 \) and \( f_2 \) can be used to classify the bottom-left examples in Figure 1 while one feature \( f_1 \) suffices for distinguishing class \( c_5 \) examples from class \( c_6 \) examples on the top-right. Reducing the retained dimensions directly correlates with the data cost of inference. To leverage inherent variances across different input space partitions, and by selecting among two experts \( E_1 \) and \( E_2 \) which respectively require \( d_1 \) and \( d_2 \) bytes per input where \( d_1 > d_2 \), decision boundaries can be determined to appropriately pass more data for more difficult inputs. Learning decision boundaries similar to those of Figure 1 can allow sensors to remotely communicate data as necessary, subject to the general position of an input within its respective

![Fig. 1: Sample space of a classification task using two features \( f_1(x) \) and \( f_2(x) \) of arbitrary inputs \( x \), where colours indicate different classes \( c_1-c_6 \). The blue line shows an instance of a learnable input space partition \( E_1(f_1, f_2) \), and the red line shows a one-dimensional classification boundary learnable by a designated expert \( E_2(f_1) \) with reduced data requirement relative to \( E_1(f_1, f_2) \).](Image 346x469 to 521x616)
space. This reduces the overall data cost of inference that is accurate enough for the task at hand. Consequently, this in turn can relieve unnecessary load on communication resources that exist between sensors and remote machines used for visual inference. Our work proposes a solution to learning such decision boundaries directly from data for any set of pretrained experts, and for any specified limit on data cost. Our contributions are summarised below:

1) We introduce a novel class of mixtures-of-experts, wherein some experts are favored to others by design. When experts of different data requirements are included, this allows mixtures to meet different constraints on allowed data utility.

2) We propose two methods to train biased mixtures such that input space is effectively partitioned for each expert to realize data-efficient mixtures.

3) We show that data transfer optimization between visual sensing and processing can be formulated as a convex optimization problem, and present an ablation study of the benefit of biased mixtures under different contexts of allowed limits on data utility.

The expert utility biasing method proposed in this paper can be applied to reduce the data cost of any model wherein the size of inputs can be subsampled or reduced. To illustrate this, we train and validate on a variety of tasks spanning multiple domains. Specifically, we validate on the tasks of: single shot object detection from the work of Wei et. al [25], realtime video action classification from the work of Zhang et. al in [53] and Chadha et. al [8], and image super resolution from the work of Shi et. al [42] and Dong et. al [11]. The remainder of this paper is organized as follows: In Section II we give an overview of recent work on rate and complexity optimization. Section III details the proposed biased expert selection and describes its general architecture and how it is trained. In Section IV we evaluate the performance of the proposed method on all tasks, and illustrate the benefits that biased mixtures of experts can provide on multiple models for each task. Finally, Section V summarises our findings and outlines possible directions for future work.

II. RELATED WORK

Within the field of compact image representation, and in order to communicate data-efficient codes across networks for remote processing, directly engineered compression techniques were extensively studied to culminate in existing image compression standards [32], [36]. More recently, learned methods [33], [49], [50] have attracted attention as the next step towards more data-driven image compression. Salient among recent advances in this domain are variational autoencoders [2], [31], [37] and adversarial models [10], [14], [35]. In order to adapt learned codes to arithmetic coders, state-of-the-art proposals on learned compression [30], [34], [38], [49] additionally learn context models to predict posteriors of latent code components conditional on all preceding components. Specifically, and to move learned compression closer to replacing established coders [32], [36], context models [30], [38] use tractable masked convolutions to regulate entropies of obtained image representations such that they can be coded more effectively by subsequent entropy coders. In distributed systems of visual analysis, and in order to reduce throughput requirements on input, latent states of learned image reconstruction machines [2], [14], [31], [35] and entropy regulated compressors [30], [33], [38], [49] can be used instead of full-length inputs as representative signals to remote inference models.

Other studies consider the regulation of input volumes for complexity optimization, and propose modifications that are applicable to a wide range of models. In this realm, proposals such as static model pruning [15], [16], [19], reduce complexity by modifying models in a persistent manner for all inputs at test time. More recent proposals [3], [4], [23], [41] show how the test-time complexity of very large networks can be substantially reduced by conditioning computation to the content of feature maps at runtime, and do so by training external agents to enable or disable different parts of models subject to the unique properties of each input. However, all of the aforementioned works optimize solely for complexity, and always consider the maximum amount of input to be available at test time. Other proposals also studied specific vision tasks in order to reduce the data requirement of deep neural network models. For example, this can be seen in previous work [8], [53], [55], where input volumes are reduced by distilling input sequences to their most useful elements before relaying to remote servers for semantic analysis. Other work [22], [52] mainly focused on task-specific mappings of inputs onto lower-dimensional space before training with more data-efficient models, and recent advances in domain adaptation and transfer learning [26], [59], [48] can also be used to learn compressed codes tuned to particular models. However, for any specified source distribution, domain adaptation [26], [59], [48] and other proposals mentioned above [8], [53], [55] equally compact all sampled inputs to fixed length codes, and varying degrees of entropy among input examples are ignored. As such, low-entropy inputs (which contain less information relative to others) are mapped to redundantly long code-lengths, and subsequently incur unnecessary loads on data transfer assets and inference complexity. In this sense, while the aforementioned advances are important in determining useful transformations to fixed-length codes, complementary techniques are necessary to determine required code lengths prior to compression and inference.

In our work, we consider the data cost optimization problem in a task-agnostic manner, and determine required input volumes prior to visual inference. Specifically, we consider how input space partitions vary in the amount of data required per input in order to ensure good performance, and leverage this variance to train more data-efficient mixtures of experts. To do so, we take inspiration from recent work [19], [23], [41] to propose a mixture of experts where expert utility is biased towards specific experts. While meeting predefined constraints on expert utility bias, we train a sparse gating function to select the most adequate expert to use from a set of experts of varied input requirements. Importantly, our method does not modify any pre-existing methods for complexity optimization or task-specific data cost reduction. As such, our proposal can be applied in conjunction with recent proposals on learned
2 we illustrate some examples of how biased mixtures can be propagated through the gating function exclusively. In Figure before training the mixture, and loss functions of \( y \) are able to activating others. In addition, all experts are optimized only when needed, and activating some experts is more favor- ...

Mixtures-of-Experts (BMoE) paradigm, experts are activated a provisioned ground-truth and trained using a task loss that calculates the error between ingests sub-sampled inputs). Mixtures-of-experts are typically included in the total loss to encourage bias, and (ii) a soft regularization approach where a regularization term is meeting the specified bias, and we describe in detail each method in the following:

III. BIASED EXPERT SELECTION

A. General Architecture Formulation

Let \( E \) denote a mixture of \( N \) experts where \( E = \{E_1, E_2, ..., E_N\} \), and each expert \( E_n \) is a modified variant of a task-performing baseline model. Per input \( x \), a gating function determines the contribution of the \( n^{th} \) expert as:

\[
G(x; W_g)_n = \frac{e^{f(x; W_g)_n}}{\sum_{m \neq n} e^{f(x; W_g)_m}}
\]

where \( W_g \) is a set of trainable weight parameters, \( m \) denotes remaining gate indices, and \( f(x; W_g) \in \mathbb{R}^N \) is the output of a specified gating model (e.g., a multi-layer perceptron). The output \( y \) of the mixture is:

\[
y = \sum_{n=1}^N G(x; W_g)_n, E_n(P_n(x))
\]

where \( P_n \) is a preprocessing function to accommodate \( x \) for the \( n^{th} \) expert (e.g., \( P_n \) performs subsampling if \( E_n \) ingests sub-sampled inputs). Mixtures-of-experts are typically trained using a task loss that calculates the error between a provisioned ground-truth and \( y \). In our proposed Biased Mixtures-of-Experts (BMoE) paradigm, experts are activated only when needed, and activating some experts is more favorable to activating others. In addition, all experts are optimized before training the mixture, and loss functions of \( y \) are back-propagated through the gating function exclusively. In Figure 2 we illustrate some examples of how biased mixtures can be applied to different tasks.

To adjust mixtures for biased expert selection, we denote the desired amount of bias in expert selection by \( b \), where each of its components \( b_n \) specifies per batch the ratio of input examples to pass to each \( n^{th} \) expert. Importantly, elements of \( b \) denote frequencies of use as ratios and cannot be assigned negative values (e.g., setting \( b_n = 0.1 \) to use expert \( E_n \) 10% of the time), giving the properties \( 0 \leq b_n \leq 1 \) and \( \|b\|_1 = 1 \). We consider two methods of training for biased expert selection: (i) a soft regularization approach where a regularization term is included in the total loss to encourage bias, and (ii) fixing the average data cost per batch, by enforcing a constant number of training examples to each expert in accordance with \( b \) and training only with respect to the task loss. Both methods encourage mixtures of experts to maximize performance while meeting the specified bias, and we describe in detail each method in the following:

B. Soft Bias Regularization

When using soft bias regularization, the most suitable expert to use is selected per input via a sparse gating function, and all other experts are omitted. To do so, akin to \( \text{41} \) for each input \( x \) only the expert associated with the highest gate value is considered for inference, and we write the sparse gating function as:

\[
G(I; W_g)_n = \psi(f(I; W_g)_n) \cdot \frac{e^{f(I; W_g)_n}}{\sum_{m \neq n} e^{f(I; W_g)_m}}
\]

where \( \psi(f(I; W_g)) \) is a non-linear operator which returns a one-hot vector indicating the top value in \( f(I; W_g) \). From \( \text{3} \) we also define the utility of each \( n^{th} \) expert \( u_n \) as its total contribution per batch \( X \) comprising \( M \) examples:

\[
u_n = \frac{1}{M} \sum_{x \in X} G(x; W_g)_n
\]
and we calculate the bias regularization loss $l_{bias}$ as a function of $u$ and the specified bias vector $b$:

$$l_{bias} = -w_{bias} \log(1 - \frac{1}{\sqrt{2}}||u - b||_2)$$

(5)

where $w_{bias}$ is a hyperparameter to control the amount of bias to impose on the mixture. Since $u$ and $b$ describe frequencies as ratios and $||u||_1 = ||b||_1 = 1$, the distance $||u - b||_2$ is normalized by $\sqrt{2}$ to ensure the expression within the log function is always positive ($\sqrt{2}$ is the maximum possible euclidian distance between vectors with an $L_1$ norm of one).

By applying the modifications to the gating function in (3), and including the bias regularization loss in (5) to the total loss, the mixture of experts is simultaneously trained to maximize task performance and meet the specified bias.

C. Batchwise Bias Enforcement

In our second proposal, rather than encourage mixtures to align the utility of their experts with the specified bias, we enforce bias per batch in accordance with $b$, and train the mixture only with respect to its task loss. This in effect trains mixtures to make better expert selections for each input, while meeting the bias constraint for every batch. Specifically, with a batch size of $M$, batches are segmented such that $Mb_n$ examples are passed to each $n^{th}$ expert. To do so, starting from (1), we consider $G \in \mathbb{R}^{M \times N}$ as an $M$ sized batch of gate vectors $G(x; \mathcal{W}_g)$, and perform the procedure described in Algorithm 1. For each $n^{th}$ expert, we denote gate values assigned to columns of input as $G_{:,n}$ and illustrate this in Figure 3.

Algorithm 1 Batchwise Bias Enforcement

Input: Soft gates batch $G \in \mathbb{R}^{M \times N}$

1: for $n = 1$ to $n = N$ do
2: \hspace{1cm} $K \leftarrow Mb_n$
3: \hspace{1cm} Calculate number of inputs to pass to the $n^{th}$ expert
4: \hspace{1cm} $T \leftarrow \text{TopK}(G_{:,n}, K)$
5: \hspace{1cm} Find top $K$ values corresponding to the $n^{th}$ expert
6: for $i = 1$ to $i = M$ do
7: \hspace{2cm} if $T_i \neq 0$ then
8: \hspace{3cm} $G_{i,j} \leftarrow 0 \ \forall j \neq n$
9: \hspace{3cm} For the $i^{th}$ input, set all gate values not corresponding to $n^{th}$ expert to 0
10: \hspace{2cm} else
11: \hspace{3cm} $G_{i,n} \leftarrow 0$
12: \hspace{3cm} Set gate value corresponding to the $i^{th}$ input and $n^{th}$ expert to 0
13: end if
14: end for
15: end for

D. Selecting Bias Values for Data Cost Optimization

So far, we discussed how biased mixtures are trained to make informed expert selections when a bias vector $b$ specifies the frequency of expert utility. Here we detail our method for selecting useful biases that can optimize performance under different constraints on data utility. We consider the inference data cost vector $d$, where each of its components $d_t$ is the size of input volumes per example as seen by each expert (i.e., the data cost associated with $P_n(x)$). When mixtures are biased, and an ample number of samples is considered, the average data cost is then expressed as $\bar{d} = bd^T = \sum_{n=1}^{N} b_n d_n$. In this way, the biasing vector $b$ can be tuned to allow for different average data costs of inference in the interval $[d_{min},d_{max}]$, where $d_{min}$ and $d_{max}$ are the minimum and maximum amounts of data that can be ingested by experts in the mixture.

Importantly, it can be seen that when $N > 2$ there can be multiple instantiations of $b$ that produce the same average data cost $\bar{d}$. Thus, when an average data cost target $d_t \in [d_{min},d_{max}]$ is specified, it is necessary to define a method by which to determine an appropriate bias vector $b$ that is subsequently used in training biased mixtures. To address this, we consider $p$ where $p_n$ quantifies the performance of each optimized expert prior to inclusion in the mixture, and select $b$ such that: (i) $b$ satisfies $d = bd^T = \sum_{n=1}^{N} b_n d_n$, and (ii) $b$ maximises the expected test performance as measured by $bp^T$. That is, when each component $p_n$ denotes an appropriate performance measure for the $n^{th}$ expert on a designated set of inputs isolated from testing examples (e.g., $p_n$ can be accuracy for classification tasks, or mean average precision for objection detection tasks), $bp^T$ is a measure of performance when samples are assigned to experts with respect to $b$. In doing so, we reduce the problem of determining $b$ for a specified data cost $d_t$ to a linear optimization problem that achieves $bd^T = d_t$, while maximising $bp^T$. Since $||b||_1 = 1$ and $b_N$ can be expressed as $b_N = 1 - \sum_{n=1}^{N-1} b_n$, by expanding and substituting $b_N$ we get the constraint:

$$b_1 d_1 + b_2 d_2 + ... + (1 - \sum_{n=1}^{N-1} b_n) d_N = d_t$$

(6)

and following that components of $b$ must be summable to unity, we also get the additional $(N-1)$ constraints:

$$b_1 \leq 1; \ b_2 \leq 1; \ldots; \ b_{N-1} \leq 1$$

(7)

with the performance maximization objective:
\[
\max \{b_1p_1 + b_2p_2 + \ldots + b_Np_N\} \quad (8)
\]

Note that (6) and (7) define \( N \) linear constraints to maximize the objective (8) with \( N \) basic values \( \{b_1, b_2, \ldots, b_N\} \). Following the duality property of such convex problems [5], [13], we can also formulate the dual (and equivalent) problem that finds \( b \) for any specified performance target \( p_t \). That is, appropriate biases can be found to meet \( p_t \) with the \( (N-1) \) constraints of (7) and the additional constraint on expected performance:

\[
b_1p_1 + b_2p_2 + \ldots + \left(1 - \sum_{n=1}^{N-1} b_n\right)p_N = p_t \quad (9)
\]

with the data cost minimization objective:

\[
\min \{b_1d_1 + b_2d_2 + \ldots + b_Nd_N\} \quad (10)
\]

Thus, determining \( b \) is a convex problem that can be readily solved by any convex optimization technique [5], [6], [13], such as the simplex method [5], [6]. That is, an appropriate biasing value \( b \) to use for training can be found for any specified target data cost \( d_t \) by solving for \( b \) in (6)-(8), or any target on expected performance \( p_t \) by solving (7), (9), and (10).

E. Final Observations

In considering the performance of biased mixtures, the quality of expert selections from \( E \) is regulated by the complexity of the gating function \( G(x; \mathcal{W}_g) \); where increasing the complexity of \( G(x; \mathcal{W}_g) \) can improve selections (e.g., by increasing the number of learnable weights), albeit with diminishing returns. In addition, and in the case of bias enforcement, we intuitively expect the quality of selections to be directly correlated with batch sizes used for training. That is, low batch size settings may not expose gating functions to a sufficient amount of variance in inputs to make selections of benefit, and setting higher batch sizes is favorable.

Importantly, applications of biased mixtures allow gating functions \( G(x; \mathcal{W}_g) \) to wholly observe inputs \( x \) prior to selecting experts for data-economy. That is, biased mixtures can be distributed such that they allow for gating before preprocessing to produce sampled inputs \( P_n(x) \), and before inputs are subsequently sent to remote models for visual inference (as illustrated in Figure 2). As a result, the constraint for gating functions is not input size, but the processing capability on-board visual sensors. We also note that, the expert selection methods detailed in Section III can be applied on mixtures comprising experts optimized via additional task-specific dimensionality reduction methods, and can also be applied on experts that use different modalities to make their inferences (as illustrated in (c) of Figure 2). Finally, while our work studies the problem of reducing data utility, \( b \) can also be specified to prioritize any other expert property whenever constraints are properly quantified and made available to the proposed gating architecture (e.g., to meet constraints on power consumption or latency).

IV. Evaluation

A. Benchmarks and Evaluation Method

To show how biased mixtures can optimize data costs of inference for different problems, we evaluate on three computer vision tasks: (i) object detection, (ii) image super resolution, and (iii) realtime action classification. In reporting results for all tasks, we compare our method against two alternatives:

1) Previously Proposed Models: To benchmark our results against relevant task-specific solutions, we consider the performance of constituent experts when optimized for different data cost constraints. In biased mixtures, this corresponds to specifying \( b \) as a one-hot vector, and measures performance when the same amount of data is used for all inputs during inference (e.g., when \( b = [0, 1, 0] \) only \( E_2 \) is used for inference). We report this to benchmark against previous work and to highlight the benefit of uniquely dividing the input space for each expert.

2) Random Selection: Here, experts are randomly selected for inference at test time in order to satisfy the model biasing requirement \( b \). This is to serve as the lower bound of performance when biased mixtures are used and the specified expert utility bias is met.

Importantly, when considering the problem of task-agnostic model optimization under data cost constraints, there is no previous work similar to ours (see Section II). That is why, we benchmark against the maximum performance achievable by recently proposed task-specific solutions when their input volumes are adjusted to meet different constraints on data cost. That is, biased mixtures consist of experts that also stand in as external benchmarks. To highlight the latter, benchmark results of constituent experts are indicated in comparative plots by markers on dotted lines.

For clarity, and to ensure consistency of representation across all tasks, we report the per input data cost of inference \( \tilde{d} \) as the average amount of data seen by the mixture after inputs are fully decompressed. For each evaluated task we specify how the data cost for each expert \( d_t \) is measured (i.e., the data cost associated with \( P_n(x) \)). For a concise measure of how well models perform across different specific data cost constraints of \( d_t \in [d_{\min}, d_{\max}] \), and with \( p_{\text{mean}}(d_t) \) denoting test performance when the target data cost is \( d_t \), we report the area under curve when data cost is normalized as:

\[
\rho = \int_0^1 p_{\text{mean}}(d_{\min} + t(d_{\max} - d_{\min})) \, dt \quad (11)
\]

For all mixtures, we specify the gating model (i.e., \( f(x; \mathcal{W}_g) \)) as a single conv-pool layer followed by a fully connected network. To ensure that the model selection process is of low complexity for all tasks, we use ReLU activated depthwise separable convolutions [43], and report the per input number of multiply-accumulate gating operations \( C_g \). We use cross-validation to optimize the biasing weight \( \nu_{\text{bias}} \) and report the best performance when soft regularization is used. After all experts included in the mixture are individually optimized, biased mixtures are trained by updating the weights of the
gating function exclusively, and the weights of experts are not fine-tuned further. We have found that using higher batch sizes is helpful when training biased mixtures, because it exposes the mixture to a more varied set of input examples to partition to each expert meaningfully. Therefore, to ensure gating functions learn meaningful features for batch partitioning, for all tasks we set the batch size to 128 and the learning rate to $10^{-4}$.

### B. Single-Shot Object Detection

We test our method on single-shot detection (SSD) to reduce the data requirement for object detection while maintaining high accuracy. Recent work [19], [20], [51] showed that SSD models vary widely in performance and complexity when input sizes are adjusted. When considering the varying degrees of complexity of natural images, we expect that the minimum required subsampling rate of inputs for accurate object detection should vary accordingly. To demonstrate this, we train a biased mixture of experts where each expert is optimized for a different image subsampling rate, and use the recent work of Liu et al. [25] as a baseline for all experts (for an illustration, see (a) of Figure 2). When the resolution of inputs to each expert is $R_n \times R_n$ pixels, we measure the data cost associated with $F_n(x)$ as $3 \times R_n \times R_n \times K$, where $3$ is the number of color channels in RGB inputs, and $K$ is the number of bytes needed to store floating point decimals.

We use VGG16 [12] and ResNet50 for feature extraction and evaluate all models using 300 regional proposal boxes for VGG16 [12], and 50 regional proposal boxes for ResNet50. Following recent work [20], [25], we train on COCO training data while excluding the 8k mini-eval images used in the 2012 challenge [24], and report performance as the mean Average Precision (mAP) on COCO (07+12). We train mixtures for 20k steps to show our results when using soft regularization and bias enforcement, and in Table I we detail the types and complexities of all layers used in devising the gating model $f(x; \mathcal{W}_g)$. Inputs to the gating model are pre-processed as $224 \times 224$ center crops of $300 \times 300$ images, and we ensure that the gating complexity of all mixtures remains at $C_g < 10^8$ Multi-Add operations.

| Feature Extractor | Biasing Method | mAP$d$ (%) when $d_i = \min d_{max}$ | $\rho$ |
|-------------------|----------------|-----------------------------------|------|
| VGG16             | Benchmark Experts | 80.0 | 70.9 |
|                   | Proposed & Enforcement | 72.5 | 70.9 |
|                   | Soft Regularization | 67.1 | 65.0 |
|                   | Random Selection | 66.3 | 65.4 |
| ResNet50          | Benchmark Experts | 75.7 | 65.1 |
|                   | Proposed & Enforcement | 67.8 | 65.9 |
|                   | Soft Regularization | 62.2 | 59.9 |
|                   | Random Selection | 61.9 | 57.4 |

Table I: Single shot detection comparison on COCO [24] of biased mixtures of SSD [25] experts against other benchmarks. Resolutions $\{R_n\}$ and data costs $\{d_n\}$ are reported for all experts.

Figure 4 shows the relationship between imposed bias, data cost, and mAP when three VGG16 experts are used for single shot detection, where the resolution of inputs to each expert is $\{R_n\} = \{100, 150, 300\}$ (Pixels); $\{d_n\} = \{120, 270, 1080\}$ (KB).

### Table II: Relation between gating complexity, batch size, and performance when bias enforcement is used.

| $C_g$ (Mult-Adds) | $M$ | $\rho$ when $\{R_n\} = \{100, 150, 300\}$ (Pixels) |
|------------------|-----|-----------------------------------------------|
| VGG16            | 16  | 68.40 64.11 69.27 64.46 |
| ResNet50         | 32  | 70.35 65.89 70.25 65.57 |
| VGG16            | 64  | 70.93 66.24 71.16 65.72 |
| ResNet50         | 26,194,304 | 71.49 67.25 72.50 67.41 |
| VGG16            | 38,700,216 | 71.84 67.59 72.97 68.04 |

Notably, biased mixtures optimized with bias enforcement provide the slowest degradation in mAP for lower data costs, with diminishing gains when more data is available at test time. Specifically, biasing via enforcement outperforms individual experts by 7.5% when an average of 220 kilobytes per image is allowed, which is equal to the performance of individual experts at 490 kilobytes. That is, when the minimum acceptable mAP is 70%, a reduction of 270 kilobytes in required data is achieved by our proposal (which is equivalent to a saving of 55% in bitrate).

In Table II we show the performance of biased mixtures when applied to multiple models, and report $\rho$ as a comprehensive measure of model performance across data costs. When compared to random selection, we note that for both ResNet50 and VGG16, imposing bias on mixtures provides the highest gain when lower values of data cost are considered (e.g., when $d_i < \min d_{max}$). Compared to soft regularization, and for all mixture configurations, we found that bias enforcement is a much more effective method for training biased mixtures (this is also true for all other tasks evaluated). We hypothesise this is because, when bias enforcement is used only the task loss is back-propagated during training, which causes less competition between losses and therefore less local minima to exist in solution space.

To further assess how biased mixtures learn useful bifurcations of input space, Table II details the performance of each expert on their assigned subset of inputs. Notably, Table V highlights how easier input examples are passed to the data-efficient expert $E_1$, resulting in increased accuracies of $E_1$ compared to its baseline accuracy 57.91%, which is measured over all test inputs of COCO [24]. Conversely, biased mixtures pass more difficult examples to $E_2$ and $E_3$, resulting in lower accuracies over their assigned inputs compared to their baseline accuracies. Interestingly, and especially for bias enforcement, Table V also shows how improved accuracies of $E_1$ (which correlate with how “easy” its assigned inputs are to classify) are inversely proportional to the number of examples passed to it, as reflected by $b_1$ (e.g., a difference of +12.72 percentile points in accuracy when $b_1 = 0.8$, compared to an increase of +18.31 when $b_1 = 0.5$).

In Table II we study the effect of adjusting the gating complexity $C_g$, batch size $M$, and number of experts $N$ on the performance of biased mixtures when bias enforcement is used. When we consider all mixtures, we find that batch size is critical to performance. This is because bias is enforced on a per batch basis, and to make meaningful decisions the gating
Fig. 4: Single shot detection performance comparison of biased mixtures of VGG16 experts against other benchmarks when \( \{ R_n \} = \{100, 150, 300 \} \). The performance of individual experts is shown on the dotted line.

TABLE III: Layer complexities \( C \) of the gating model \( f(x; W_g) \) for biased mixtures evaluated on single shot detection. Expert input resolutions are specified as \( \{ R_n \} = \{100, 150, 300 \} \) and \( N = 3 \).

| Layer Type       | Filter Shape | Stride | Input Shape              | \( C \) (Mult-Adds) |
|------------------|--------------|--------|--------------------------|---------------------|
| Convolutional    | \( 3 \times 3 \times 3 \times 64 \) | 2      | \( 224 \times 224 \times 3 \) | 2,747,136           |
| Avg. Pooling     | 7 \times 7   | 5      | \( 111 \times 111 \times 64 \) | ---                 |
| Flatten Op.      | -            | -      | \( 1 \times 232 \times 64 \) | ---                 |
| Fully Connected  | \( 28 \times 224 \times 1024 \) | -      | \( 1 \times 29224 \) | 28,901,376          |
| Fully Connected  | 1024 \times 3 | -      | \( 1 \times 1024 \) | 3072                |

function needs to be exposed to an ample amount of variance between examples. We also see that increasing the complexity of gating does increase performance by helping partition the input space more effectively. However, this effect saturates at \( C_g \approx 3.8 \times 10^7 \) Multi-Add operations, which demonstrates that the optimal hyperplane to partition input space for \( N \leq 3 \) experts can be learned with low complexity.

By comparing the left and right part of Table III we see that adding more experts to the mixture provides a modest increase to performance. This is because having more experts allows the mixture to further exploit the variance in different input sub-spaces (if any such variance exists). To see the extent to which this is true, in Figure 5 we adjust the limits of allowed input resolutions to the mixture \( R_{min} \) and \( R_{max} \), and report \( \rho \) when considering different values of \( N \). Importantly, we see that when the difference between \( R_{min} \) and \( R_{max} \) is lower, using more experts yields less gain in performance, to the point where using more than three experts for \( \{ R_{min}, R_{max} \} = \{100, 300\} \) does not provide any benefit. This is because, while setting high values of \( N \) increases the number of intermediate resolutions between \( R_{min} \) and \( R_{max} \), the difference \( (R_{max} - R_{min}) \) correlates with the amount of discernable adequacy between experts, which in turn correlates with the benefit of including more experts.

C. Image Super-Resolution

We test the applicability of biased mixtures on Single Image Super resolution (SISR), an image reconstruction task where spatial features of high-resolution images are inferred from low-resolution input images. Several recent proposals have shown good performance in terms of image reconstruction accuracy and computational efficiency [11], [42], [47], [54]. However, current super resolution models do not take into account the variable amount of high-frequency edge content between images. That is, when reconstructing images which contain many high frequency elements, SISR models are likely to benefit from higher resolution input images, while images comprising predominately low-frequency content can be inferred just as well from lower resolution inputs. This is true also when considering different parts of an image, which usually vary in the breadth of their frequency elements. To demonstrate this, we train biased mixtures to determine the needed input resolution for good image reconstruction, and in doing so, we show how different image parts can be adaptively upscaled subject to their content. Such decisions about selected super-resolution experts can also be augmented to existing media streaming standards (e.g., DASH/HLS in HTTP [19]) for adaptive subsampling prior to transmission.

We evaluate on the NTIRE17 challenge dataset DIV2K [1], and use state-of-the-art proposals on super-resolution [11], [42] as baselines for constituent experts of biased mixtures. To expose biased mixtures to the intra-image variance of frequency elements, images are divided using a fixed grid into parts of size \( 64 \times 64 \) pixels, and super-resolution is performed on each part separately (for an illustration, see (b) of Figure 2). By inspecting the low-level semantics of each image part, the mixture selects the most data efficient expert for reconstruction to preform an upsampling from the set \( \{ S_n \} = \{ \times 4, \times 3, \times 2 \} \). For each expert that upscals inputs with a factor of \( S_n \) to match the target resolution of \( 64 \times 64 \) pixels, we measure the associated data cost as \( d_n = (64/S_n)^2 \times K \), where \( K \) is the number of bytes needed to store floating point decimals. To expose gating to the high frequency components of input images, inputs to the gating model are not subsampled, and are...
maintained at the original resolution of resolution of $64 \times 64$ pixels. For all biased mixture results, mixtures are trained for 20 epochs and we ensure the complexity of the gating function is set to $C_g < 10^7$ Mult-Add operations.

![Graph showing PSNR vs d(kB)](image)

**Fig. 6:** Super resolution performance comparison of biased mixture of ESPCN [42] experts and other benchmarks when $\{S_n\} = \{\times 4, \times 3, \times 2\}$.

**TABLE IV:** Image super resolution comparison on DIV2K [11] of biased mixtures and other benchmarks. Upscale factors $\{S_n\}$ and data costs $\{d_n\}$ are reported for all experts.

| Model       | Basing Method               | PSNR (dB) when $d = \{d_{\min}, d_{\max}\}$ | $\rho$ |
|-------------|-----------------------------|---------------------------------------------|--------|
| ESPCN [42]  | Benchmark Experts [42]      | $30.4, 28.4$                               | 90.7   |
|             | Proposed b Enforcement      | $30.7, 28.8$                               | 110.0  |
|             | Soft Regularization [41]    | $30.0, 28.4$                               | 106.0  |
|             | Random Selection            | $29.8, 28.0$                               | 103.0  |
| F-SRCNN [11]| Benchmark Experts [11]      | $30.1, 28.3$                               | 105.0  |
|             | Proposed b Enforcement      | $30.1, 28.3$                               | 105.0  |
|             | Soft Regularization [41]    | $29.3, 27.6$                               | 101.0  |
|             | Random Selection            | $29.2, 27.5$                               | 100.0  |

In Table IV we compare biased mixtures against other benchmarks when using ESPCN [42] and FRSCNN [11] as baselines, in Table VI we detail the performance of experts over their assigned subsets of input, and in Figure 6 we show the relationship between average data cost and PSNR when considering ESPCN [42]. Notably from Figure 6 when bias enforcement is used and $d$ is within the range of 18-22 kilobytes, biased mixtures outperform single experts with an average difference of 0.4 dB. Over the same range of values of $d$, and when compared to random selection, bias enforcement provides an average improvement of 0.7 dB. This highlights the magnitude of intra-image high variance in required input resolution for image reconstruction, which is not considered by random selection and optimized experts. Overall, Figure 6 and Table IV show that biased mixtures outperform individual experts most when $d < 20$ kilobytes, with diminishing gains in performance for higher values of $d$. Consistent with our observations on object detection, Table VI shows how easier inputs are passed to the data-efficient super-resolution model $E_1$, thereby increasing its reconstruction accuracy, while more difficult examples are passed to $E_2$ and $E_3$ resulting in a modest reduction of their PSNR performance.

![Image showing expert assignments to different images](image)

**Fig. 7:** Examples of expert assignments to different image parts. Selected and non-selected experts are respectively highlighted by blue and red borders. Note the exploitable variance in detail between images, which translates into the data cost savings reported in Table IV.

**TABLE V:** Layer complexities $C$ of the gating model $f(x; W_g)$ for biased mixtures evaluated on single image super-resolution. Expert upsampling factors are specified as $\{S_n\} = \{\times 4, \times 3, \times 2\}$ and $N = 3$.

| Layer Type     | Filter Shape | Stride | Input Shape | $C$ (Mult-Adds) |
|----------------|--------------|--------|-------------|-----------------|
| Convolutional  | $3 \times 3 \times 3 \times 64$ | 2      | $64 \times 64 \times 3$ | 224, 256       |
| Avg. Pooling   | $3 \times 3$ | 2      | $21 \times 21 \times 64$ | —              |
| Flatten Op.    | —            | —      | $10 \times 10 \times 64$ | —              |
| Fully Connected| $6400 \times 512$ | —     | $6400$ | 3,276, 800 |
| Fully Connected| $512 \times 3$ | —     | $1 \times 512$ | 1,536          |

In Figure 7 we show examples of expert selections made by the biased mixture to resolve different $64 \times 64$ inputs when bias enforcement is used. The mixture learns to pass image parts with high frequency components to the $\times 2$ SISR model, and passes other less demanding parts to the $\times 4$ model (which are blurrier, due to the lower frequency of their components).

**D. Realtime Action Classification**

We validate biased expert selection on realtime video action classification in the compressed domain. While the best performing action classification models operate on uncompressed video data, to reduce latency, the models proposed in recent work approximate a low-resolution optical flow from codec motion vectors at high speeds for action classification. The classifiers of use two-stream architectures to infer actions, where spatial and temporal classifiers complement each other by learning different sets of features from their respective domains. As such, for some action subsets, the use of only the spatio-temporal or spatial classifier can suffice in drawing accurate distinctions between actions, but combining the predictions of both yields the highest accuracy.

Distinct from other compute-exhaustive models for action classification, recent proposals on realtime video classification use minimal volumes of data to ensure complexities and runtimes remain low. Moreover, and in order to bypass complexity overheads associated with dense optical flow estimation,
the proposals of produce spatio-temporal modes (which we hereon refer to as temporal modes for brevity) directly from compressed bitstreams. To show how biased mixtures can be applied in multi-modal settings, we expose temporal modes of video to gating functions that appropriately select which modes are used for subsequent classification. That is, prior to sending inputs to remote realtime classification models, we show how gating functions of biased mixtures can opt to use modalities only when they are needed for accurate classification (and we illustrate this in (c) of Figure 2). By doing so, we show how biased mixtures can learn to leverage modal variance to mitigate unnecessary traffic between sensors and remote classifiers.

We evaluate on UCF-101 [45] and measure the cost associated with the spatial mode as $F \times H_s \times H_s \times W_s \times K \times 3$, where $F_s$ is the number of RGB frames used, $H_s = 360$ and $W_s = 240$ are the height and width of inputs, 3 is the number of color channels, and $K$ is the number of bytes to store floating point decimals. For the temporal model, we measure the data cost as $F_t \times H_t \times W_t \times K \times 2$, where $F_t = 150$ is the number of frames used, $H_t = 24$ and $W_t = 24$ are the height and width of motion vector maps, and 2 is the number of channels used to represent vertical and horizontal motion. Importantly, we select spatial sampling rates akin to those of [8] which sets $F_s = 1$, $F_t \geq 10$, and the proposal of [53] which sets $F_s = 1$, $F_t \geq 100$. This is to meet complexity limits for realtime inference, where the benchmark models set modest sampling rates compared to other exhaustive methods [7], which typically use dense optical flow approximations with $F_s \geq 25$ and $F_t \geq 250$. Moreover, in implementing the benchmark model of Zhang et al. [53], we follow their method of upsampling $24 \times 24$ motion vector maps to $224 \times 224$ temporal mode inputs, and we specifically use a nearest-neighbours upsampling filter. Inputs are upsamples after they are sent via the $(\ast)$ operator of Figure 2 (c), and therefore input shape parameters remain at $H_t = 24$ and $W_t = 24$ when measuring data cost.

For data-exhaustive action classification, we use fusion classifiers which combine both modalities to predict actions with the highest possible accuracy. Fusion classifiers incur a data cost equal the sum of both modalities. We include all modalities to train biased mixtures of experts, where $\{\text{Mode}_n\} = \{\text{Temporal, Spatial, Fusion}\}$. Importantly, and to allow for lower complexities of gating, inputs to the gating model include only the temporal modes of videos, and spatial modes are not used. For all biased mixtures, we train for 80k steps and restrict the complexity of the gating function to $C_g < 10^8$ Mult-Add operations, where we detail the layer-wise complexities of gating in Table VII.

| Model | Biasing Method | Accuracy($d_f$) (% when $d_f = d_{\text{max}}$) | $d_{\text{max}}$ ($\frac{d_{\text{max}}}{d_{\text{max}}}$) | $\rho$ |
|-------|----------------|-------------------------------|-----------------------------|-------|
| MV-3DCNN [8] | Benchmark Experts [53] | 88.0 | 79.0 | 77.9 | 80.9 |
| | Proposed & Enforcement | 82.6 | 80.4 | 83.3 | 83.5 |
| | Soft Regularization [51] | 80.3 | 78.0 | 81.9 | |
| | Random Selectors | 78.8 | 77.3 | 81.3 | |
| EMV-CNN [53] | Benchmark Experts [53] | 85.6 | 76.6 | 75.5 | 78.7 |
| | Proposed & Enforcement | 80.2 | 79.2 | 81.3 | |
| | Soft Regularization [51] | 77.2 | 75.6 | 79.7 | |
| | Random Selectors | 75.7 | 74.9 | 79.0 | |

In Table VII we compare the performance of biased mixtures against other benchmarks when using the spatial and temporal classifiers of [8] and [53] as baselines, and in Table VII we detail the performance of experts over their assigned input subsets as determined by $G(x; W_g)$. From Table VII we first note that both biasing methods outperform random selection, by up to 1% for soft regularization and up to 3.8% for bias enforcement. This indicates that the biased mixture learns to discern confusing classes for particular modalities to pass them to others. Notably, when $d = \frac{d_{\text{max}}}{3} = 860$ kilobytes, bias enforcement gives an accuracy 1.4% higher than that of the optimized experts at $d_{\text{max}} = 1290$ kilobytes, which requires 430 kilobytes more in data cost.

In Figure 8 we show the relationship between $d$ and action classification accuracy for instances of $b$ when biased mixtures of MV-3DCNN [8] experts are used and the mode of each expert is $\{\text{Mode}_n\} = \{\text{Temporal, Spatial, Fusion}\}$. We first note that, due to the low resolution of its inputs, the temporal classifier requires the least amount of data and can predict actions with an accuracy of 77.8%. By selecting among the three modes, both biasing methods outperform random selection, with bias enforcement increasing accuracy by up to 3.4% for when $d = 1032$ kilobytes. Notably, and when using the temporal classifier for 80% of videos at $d = 1032$ kilobytes (i.e., when $b = \{0.8, 0.1, 0.1\}$), bias enforcement is 1.6% more accurate than the spatial classifier (which requires 811 kilobytes more in data, equivalent to an increase of 78% in data cost). The latter shows the extent to which biased mixtures can improve performance by using modest amounts of data, even compared to individual models that require substantially more in data cost.

Table VII shows how inputs are appropriately passed to experts for data-economic classification. Specifically, it shows how biased mixtures learn to use the data-efficient temporal model for inputs that are easier to classify, where temporal modalities are likely to suffice for accurate classification.

TABLE VI: Realtime action classification on UCF-101 [45] of biased mixtures of experts and other benchmarks. Modalities $\{\text{Mode}_n\}$ and data costs $\{d_n\}$ are reported for all experts.

TABLE VII: Layer complexities $C$ of the gating model $f(x; W_g)$ for biased mixtures evaluated on realtime action classification. Expert modalities are specified as $\{\text{Mode}_n\} = \{\text{Temporal, Spatial, Fusion}\}$ and $N = 3$. Note that the gating model $f(x; W_g)$ ingests only temporal modalities of $x$.

| Layer Type | Filter Shape | Stride | Input Shape | $C$ (Mult-Adds) |
|------------|--------------|--------|-------------|-----------------|
| Convolutional Flatten Op. | $3 \times 3 \times 320 \times 64$ | 2 | $24 \times 24 \times 320$ | 4,303,540 |
| Fully Connected | 7744 × 1024 | 1 | $1 \times 7744$ | 7,929,856 |
| Fully Connected | 1024 × 3 | 1 | $1 \times 1024$ | 3,072 |
For example, this is evident when $b_1 = 0.5$ and $b_1 = 0.2$, where the temporal classifier $E_1$ respectively gains $+5.81$ and $+5.60$ percentile points in classifying its assigned inputs when compared to its baseline accuracy measured over all test videos of UCF-101 \[45\]. On the other hand, Table VII also shows how more difficult inputs are passed to the spatial and fusion classifiers, resulting in a modest loss of accuracy when classifying their assigned inputs. Moreover, Table VII highlights how bias enforcement is superior to soft regularization in assigning inputs to different modalities, where this is evident across all values of $b$.

![Fig. 8: Realtime action classification performance comparison of biased mixtures of MV-3DCNN [8] experts, with expert modalities \{Mode$_n$\}={Temporal, Spatial, Fusion}](image)

(a) the middle region highlights instances of different classes which are more entangled and therefore harder to classify. For a sample of instances, Figure 9 (b) shows modalities selected by the biased mixture for action classification. Notably, the biased mixture tends to select the data-exhaustive fusion mode for instances located in the entangled middle region, where inputs are harder to classify (as indicated by label 1 in (b) of Figure 9), and temporal modes are predominantly used for sufficiently isolated input clusters located outside the middle region (as indicated by label 0 in (b) of Figure 9). That is, Figure 9 shows how the biased mixture favors using the temporal classifier for video clusters that are comparatively isolated and easy to discern, while the fusion model is used when videos are more entangled and harder to classify.

For the same biased mixture that yields the t-SNE representation of Figure 9, in Figure 10 we detail the classwise percentile of videos assigned to the fusion classifier for the first 30 classes of UCF101 \[45\], where \{Mode$_n$\}={Temporal, Fusion} and $b = [0.75, 0.25]$. (a) the middle region highlights instances of different classes which are more entangled and therefore harder to classify. For a sample of instances, Figure 9 (b) shows modalities selected by the biased mixture for action classification. Notably, the biased mixture tends to select the data-exhaustive fusion mode for instances located in the entangled middle region, where inputs are harder to classify (as indicated by label 1 in (b) of Figure 9), and temporal modes are predominantly used for sufficiently isolated input clusters located outside the middle region (as indicated by label 0 in (b) of Figure 9). That is, Figure 9 shows how the biased mixture favors using the temporal classifier for video clusters that are comparatively isolated and easy to discern, while the fusion model is used when videos are more entangled and harder to classify.

For the same biased mixture that yields the t-SNE representation of Figure 9, in Figure 10 we detail the classwise percentile of videos assigned to the fusion classifier. Evidently from Figure 10 challenging inputs are typically sent to the data-exhaustive fusion mode when they contain: (i) significant camera movement, leading to noise in underlying motion flow (e.g., for $63\%$ and $57\%$ of “Biking” and “Cliff Diving” instances, respectively), and (ii) relatively static scenes, resulting in sparse motion vector maps (e.g., for $38\%$ and $32\%$ of “Apply Lipstick” and “Blow Dry Hair” instances, respectively). Hence, Figure 9 and Figure 10 show how biased expert mixtures can find useful bifurcations of input space such that only necessary modalities are used for action classification, and less data is used whenever possible.

V. CONCLUSION

We introduce biased expert utility in mixtures-of-experts for effective partitioning of input space to meet constraints on data availability at test time. We propose two methods...
for training biased mixtures, and evaluate their performance on multiple models for all investigated tasks. We show how biased mixtures are applicable to any situation wherein experts vary in data requirement and performance, and demonstrate this on a wide range of computer vision tasks (we also make public a Tensordflow-1.14 implementation of biased mixtures in https://github.com/UCL-Abbas/bmoe). Our validation shows that, especially for lower ranges of allowed data cost, biased mixtures significantly outperform baseline models optimized to meet the same constraints on available data. We also show how useful gathing inferences that prioritise data economy can be realised with complexities that do not exceed $10^8$ Mult-Add operations, which are feasible to run even on embedded computation units (e.g., ARM Cortex-M7).

Within contexts of distributed visual inference, and to meet different constraints on data transfer and bandwidth at test time, all of our observations and tests show the importance of conditioning data utility for visual inference to the local proximities and properties of inputs within their space. In other words, the importance of doing so is applicable to all presented vision tasks, and is likely to extend to other visual inference tasks in order to mitigate unnecessary burdens on communication resources and sensor hardware. We finally note that an important advantage of biased mixtures is the flexibility at which they can be applied, in that, biased mixtures do not modify their constituent experts, but rather augment their function with an input preprocessing stage that allows for data-economic inference.
