Abstract

X3SAT is the problem of whether one can satisfy a given set of clauses with up to three literals such that in every clause, exactly one literal is true and the others are false. A related question is to determine the maximal Hamming distance between two solutions of the instance. Dahlhoff provided an algorithm for Maximum Hamming Distance XSAT, which is more complicated than the same problem for X3SAT, with a runtime of $O(1.8348^n)$; Fu, Zhou and Yin considered Maximum Hamming Distance for X3SAT and found for this problem an algorithm with runtime $O(1.6760^n)$. In this paper, we propose an algorithm in $O(1.3298^n)$ time to solve the Max Hamming Distance X3SAT problem; the algorithm actually counts for each $k$ the number of pairs of solutions which have Hamming Distance $k$.

Keywords and phrases X3SAT Problem, Maximum Hamming Distance of Solutions, Exponential Time Algorithms, DPLL Algorithms

1 Introduction

Given a Boolean formula $\phi$ in conjunctive normal form, the satisfiability (SAT) problem seeks to know if there are possible truth assignments to the variables such that $\phi$ evaluates to the value “True”. One naïve way to solve this problem is to brute-force all possible truth assignments and see if there exist any assignment that will evaluate $\phi$ to “True”. Suppose that there are $n$ variables and $m$ clauses, we will take up to $O(mn)$ time to check if every clause is satisfiable. However, since there are $2^n$ different truth assignments, we will take a total of $O(2^*nm)$ time [9]. Classical algorithms were improving on this by exploiting structural properties of the satisfiability problem and in particular its variants. The basic type algorithms are called DPLL algorithms — by the initials of the authors of the corresponding papers [5, 6] — and the main idea is to branch the algorithm over variables where one can, from the formula, in each of the branchings deduce consequences which allow to derive values of some further variables as well, so that the overall amount of the run time can be brought down. For the analysis of the runtime of such algorithms, we also refer to the work of Eppstein [7, 8], Fomin and Kratsch [9] and Kullmann [14].

A variant of SAT is the Exact Satisfiability problem (XSAT), where we require that the satisfying assignment has exactly 1 of the literals to be true in each clause, while the other literals in the same clause are assigned false. If we have at most 3 literals per clause with the aim of only having exactly 1 literal to be true, then the whole problem is known as Exact 3-Satisfiability (X3SAT) and this is the problem which we wish to study. Wahlström [15]
provided an X3SAT solver which runs in time $O^*(1.0984^n)$ and subsequently there were only slight improvements; here $n$ is, as also always below, the number of variables of the given instance and $O^*(g(n))$ is the class of all functions $f$ bounded by some polynomial $p(\cdot)$ (in the size of the input) times $g(n)$. The problems mentioned before, SAT, 3SAT and X3SAT are all known to be NP-complete. More background information to the above bounds can be found in the PhD theses and books of Dahllöf [4], Gaspers [10] and Wahlström [18].

The runtime of SAT, 3SAT, XSAT and X3SAT have been well-explored. Sometimes, instead of just finding a solution instance to a problem, we are interested in finding many “diverse” solutions to a problem instance. Generating “diverse” solutions is of much importance in the real world and can be seen in areas such as Automated Planning, Path Planning and Constraint Programming [21]. How does one then measure the “diversity” of solutions? This combinatorial aspect can be investigated naturally with the notion of the Hamming Distance. Given any two satisfying assignments to a satisfiability problem, the Hamming Distance problem seeks to find the number of variables that differ between them. The Max Hamming Distance problem therefore seeks to compute the maximum number of variables that will defer between any two satisfying assignments. If we are interested in the “diversity” of exact satisfying assignments, then the problem is defined as Max Hamming Distance XSAT (X3SAT) accordingly. The algorithm given in this paper actually provides information about the number of pairs of solutions which have Hamming distance $k$, for $k = 0, 1, \ldots, n$, which could potentially have uses in other fields such as error correction.

A number of authors have worked in these area previously as well. Crescenzi and Rossi [2] as well as Anglesmark and Thapper [1] studied the question to determine the maximum Hamming distance of solutions of instances of certain problems. Dahllöf [3, 4] gave two algorithms for Max Hamming Distance XSAT problem in $O^*(2^n)$ and an improved version in $O^*(1.8348^n)$. The first algorithm enumerates all possible subset of all sizes while checking that they meet certain conditions. The second algorithm uses techniques found in DPLL algorithms. Fu, Zhou and Yin [12] specialised on the X3SAT problem and provided an algorithm to determine the Max Hamming Distance of two solutions of an X3SAT instance in time $O^*(1.676^n)$. Recently, Hoi and Stephan [20] gave an algorithm to solve the Max Hamming Distance XSAT problem in $O(1.4983^n)$.

The main objective of this paper is to propose an algorithm in $O(1.3298^n)$ time to solve the Max Hamming Distance X3SAT problem. The output of the algorithm is a polynomial $p$ which gives information about the number $a_k$ of pairs of solutions of Hamming distance $k$, for $k = 0, 1, \ldots, n$. The algorithm does so by simplifying in parallel two versions $\phi_1, \phi_2$ of the input instance and the main novelty of this algorithm is to maintain the same structure of $\phi_1$ and $\phi_2$ and to also hold information about the Hamming distance of the current and resolved variables while carrying out an DPLL style branching algorithm.

Section 4 compares the approach taken with other known methods.

## 2 Basic Approach

Suppose a X3SAT formula $\phi$ over the set of $n$ variables $X$ is given. The aim is to find the largest Hamming distance possible between two possible value assignments $\beta_1, \beta_2$ to the variables which are solutions of $\phi$, that is, make true exactly one literal in each clause of $\phi$.

To this end, the algorithm presented in this paper computes a polynomial (called $HD$-polynomial) in $u$, with degree at most $n$, such that the coefficient $c_k$ of $u^k$ gives the number of solution pairs $(\beta_1, \beta_2)$ such that the Hamming distance between $\beta_1$ and $\beta_2$ is $k$. The degree of this polynomial will then provide the largest Hamming distance between any pair of solutions.

**Example 1.** We consider the formula $\phi = (x_1 \lor x_2 \lor x_3) \land (x_1 \lor x_4 \lor x_5) \land (x_1 \lor x_6 \lor x_7) \land (x_2 \lor x_4 \lor \neg x_6)$. Exhaustive search gives for this X3SAT formula the following four
solutions:

| $x_1$ | $x_2$ | $x_3$ | $x_4$ | $x_5$ | $x_6$ | $x_7$ |
|-------|-------|-------|-------|-------|-------|-------|
| 1     | 0     | 0     | 0     | 0     | 0     | 0     |
| 0     | 1     | 0     | 0     | 1     | 1     | 0     |
| 0     | 0     | 1     | 1     | 0     | 1     | 0     |
| 0     | 0     | 1     | 0     | 1     | 0     | 1     |

So there are 16 pairs of solutions among which four pairs have Hamming distance 0 and twelve pairs of Hamming distance 4. The intended output of the algorithm is the polynomial $12u^4 + 4u^0$ which indicates that there are four pairs of Hamming distance 0 and twelve pairs of Hamming distance 4.

The reason for choosing this representation is that our algorithm often needs to add/multiply possible partial solutions, which can be done easily using these polynomials whenever needed.

The brute force approach would be to consider a search tree, with four branches at the internal nodes — $(0, 0), (0, 1), (1, 0), (1, 1)$ based on values assigned to some variable $x$ for the two possible solutions being compared. If at a leaf the candidate value assignments $(\beta_1, \beta_2)$ formed by using the values chosen along the path from the root are indeed both solutions for $\phi$ and their Hamming distance is $k$, then the polynomial calculated at the leaf would be $u^k$; if any of $(\beta_1, \beta_2)$ are not solutions then the polynomial calculated at the leaf would be 0.

Then, one adds up all the polynomials at the leaves to get the result. This exhaustive search has time complexity (number of leaves) $\times \text{poly}(n, |\phi|) = 4^n \times \text{poly}(n, |\phi|)$ for $n$ variables.

For $x \in X$ and $i, j \in \{0, 1\}$, let $q_{x,i,j}$ be $u$ if $i \neq j$ and 1 otherwise. The above brute force approach for computing the HD-polynomial would be equivalent to computing

$$\sum_{(\beta_1, \beta_2) \in X} \prod_{x \in X} q_{x,\beta_1(x),\beta_2(x)},$$

where $(\beta_1, \beta_2)$ in the summation ranges over the pair of solutions for the X3SAT problem $\phi$.

However, we may not always need to do the full search as above. We will be using a DPLL type algorithm, where we use branching as above, and simplifications at various points to reduce the number of leaves in the search tree. Note that the complexity of such algorithms is proportional to the number of leaves, modulo a polynomial factor: that is, complexity is $O(\text{poly}(n, |\phi|) \times \text{poly}(n, |\phi|))$ for $n$ variables.

As an illustration we consider some examples where the problems can be simplified. If there is a clause $(x, y)$, then $x \neq y$ for any solution which satisfies the clause. Thus, $x$ and $y$’s values are linked to each other, and we only need to explore the possibilities for $y$ and can drop the branching for $x$ (in addition one needs to do some book-keeping to make sure the difference in the values of $y$ in two solutions also takes care of the difference in the values of $x$ in the two solutions; this book-keeping will be explained below). As another example, if there is a clause $(x, x, z)$, then value of $x$ must be 0 in any solution which satisfies the clause. Our algorithm would use several such simplifications to bring down the complexity of finding the largest Hamming distance. In the simplification process, we will either fix values of some of the variables, or link some variables as above, or branch on a variable $x$ to restrict possibilities of other variables in clauses involving $x$ and so on (more details below).

In the process, we need to maintain that the HD-polynomial generated is as required. Intuitively, if we consider a polynomial calculated at any node as the sum of the values of the polynomials in the leaves which are its descendant, then the value of the polynomial calculated at the root of the search tree gives the HD-polynomial we want. For this purpose, we will keep track of polynomials named $p_{\text{main}}$ and $p_{x,i,j}$, which start with $p_{\text{main}}$ being 1, and polynomials $p_{x,i,j} = q_{x,i,j}$, for $x \in X, i, j \in \{0, 1\}$ (here $q_{x,i,j}$ is $u$ for $i \neq j$, and 1 otherwise). If there is no simplification done, then at the leaves, the polynomial $p_{\text{main}}$ will
become the product of $p_{x,i,j}$, $x \in X$, for the values $(i, j)$ taken by $x$ for the two solutions in that branch. When doing simplification via linking of variables, or assigning truth value to some variables, etc., we will update these polynomials, so as to maintain that the polynomial calculated at the root using above method is the HD-polynomial we need. More details on this updating would be given in the following section.

3 Algorithm for Computing HD-polynomial

In this section we describe the algorithm for finding the HD-polynomial for any X3SAT formula $\phi$. Note that we consider clause $(x, y, z)$ to be same as $(y, x, z)$, that is order of the literals in the clause does not matter. We start with some definitions.

Notation: For a formula $\phi$ with variable $x$, we use the notation $\phi[x = i]$ to denote the formula obtained by replacing all occurrence of $x$ in $\phi$ by $i$. Similarly, for a set $P$ containing values/definitions of some parameters, including $p_1, p_2$, we use $P[p_1 = f, p_2 = g]$ to denote the modification of $p_1$ to $f$, $p_2$ to $g$ (and rest of the parameters remaining the same).

- Definition 2. Fix a formula $\phi$:

  (a) For a literal / variable $x, x'$ and other primed versions are either $x$ or $\neg x$, i.e., they use the same variable $x$, which may or may not be negated.

  (b) Two clauses $c, c'$ are called neighbours if they share a common variable. For example, $(x, y, z)$ and $(\neg x, w, r)$ are neighbours.

  (c) Two clauses are called similar if one of them can be obtained from the other just by negating some of the literals. They are called dissimilar if they are not similar. For example, $(x, y)$ is similar to $(\neg x, \neg y)$, $(1, x, y)$ is similar to $(0, \neg x, y)$, $(x, z)$ is dissimilar to $(x, y)$ and $(\neg x, z)$ is dissimilar to $(x, \neg z)$.

  (d) Two X3SAT formulas have the same structure if they have the same number of clauses and there is a 1–1 mapping between these clauses such that the mapping maps a clause to a similar clause.

  (e) A set of clauses $C$ is called isolated (in $\phi$), if none of the clauses in $C$ is a neighbour of any clause in $\phi$ which is not in $C$.

  (f) A set $I$ of variables is semisolated in $\phi$ by $J$ if all the clauses in $\phi$ either contain only variables from $I \cup J$, or do not contain any variable from $I$. We will be using such $I$ and $J$ for $|I| \leq 10$ and $|J| \leq 3$ only to simplify some cases.

  (g) We say that $x$ is linked to $y$, if we can derive that $x = y$ (respectively, $x = \neg y$) in any possible solution using constantly many clauses of the X3SAT formula $\phi$ as considered in our case analysis (a constant bound of 20 is enough). In this case we say that value $i$ of $x$ is linked to value $i$ of $y$ (value $i$ of $x$ is linked to value $1 - i$ of $y$ respectively).

- Definition 3 (see Monien and Preis [15]). Suppose $G = (V, E)$ is a simple undirected graph. A balanced bisection is a mapping $\pi : V \rightarrow \{0, 1\}$ such that, for $V_i = \{v : \pi(v) = i\}$, $|V_0|$ and $|V_1|$ differ by at most one. Let $\text{cut}(\pi) = |\{(v, w) : v \in V_0, w \in V_1\}|$. The bisection width of $G$ is the smallest $\text{cut}(\cdot)$ that can be obtained for a balanced bisection.

Suppose $\phi$ is the original X3SAT formula given over $n$ variable set $X$. Our main (recursive) algorithm is $\text{MHD}(\phi_1, \phi_2, s_1, s_2, V, P)$, where $\phi_1, \phi_2$ are formulas with the same structure over variable set $V \subseteq X$, $s_1, s_2$ are some value assignments to variables from $X$ and $P$ is a collection of polynomials (over $u$) for $p_{\text{main}}$ and $p_{x,i,j}$, $x \in X$, $i, j \in \{0, 1\}$. Intuitively, $p_{\text{main}}$ represents the portion of the polynomial which is formed using variables which have already been fixed (or implied) based on earlier branching decisions.

Initially, algorithm starts with $\text{MHD}(\phi_1 = \phi, \phi_2 = \neg \phi, V = X, s_1 = 0, s_2 = 0, P)$, where $\phi$ is the original formula given for which we want to find the Hamming distance, $X$ is the set of variables for $\phi$, $s_1, s_2$ are empty value assignments, $p_{\text{main}} = 1$, $p_{x,i,j} = q_{x,i,j}$.
Intuitively, the function $\text{MHD}(\phi_1, \phi_2, s_1, s_2, V, P)$ returns the polynomial $p_{\text{main}} \times \sum_{(\beta_1, \beta_2)} \prod_{x \in V} p_x, \beta_1(x), \beta_2(x)$, where $\beta_1, \beta_2$ range over value assignments to variables in $V$ which are satisfying for the formula $\phi_1$ and $\phi_2$ respectively, and which are consistent with the value assignment in $s_1, s_2$, if any, respectively. Thus, if we consider the search tree, then the node representing $\text{MHD}(\phi_1, \phi_2, s_1, s_2, V, P)$ basically represents the polynomial formed

$$\sum_{(\beta_1, \beta_2)} \prod_{x \in X} q_x, \beta_1(x), \beta_2(x),$$

where $(\beta_1, \beta_2)$ in the summation ranges over the pair of solutions for the X3SAT problem $\phi$, consistent with the choices taken for the branching variables in the path from the root to the node. Over the course of the algorithm, the following steps will be done:

(a) using polynomial amount of work (in size of $\phi$) branch over some variable or group of variables. That is, if we branch over variable $x$, we consider all possible values for $x$ in $\{0, 1\}$ for $\phi_1, \phi_2$ (consistent with $s_1(x), s_2(x)$ respectively), and then evaluate the corresponding subproblems: note that $\text{MHD}(\phi_1, \phi_2, s_1, s_2, V, P)$ would be the sum of the answers returned by (upto) four subproblems created as above: where in the subproblem for $x$ being fixed to $(i, j)$ in $(\phi_1, \phi_2)$ respectively, $p_{\text{main}}$ gets multiplied by $p_{x,i,j}$ and $x$ is dropped from $V$.

(b) simplify the problem, using polynomial (in size of $\phi$) amount of work, to $\text{MHD}(\phi_1', \phi_2', s_1', s_2', V', P')$, where we reduce the number of variables in $V$ or the number of clauses in $\phi_1', \phi_2'$.

Note that all our branching/simplification rules will maintain the correctness of calculating $\text{MHD}(\ldots)$ as described above.

Thus, the overall complexity of the algorithm is $O(p\text{oly}(n, |\phi|) \times [\text{number of leaves in search tree}])$. In the analysis below thus, whenever branching occurs, reducing the number of variables from $n$ to $n-r_1, n-r_2, \ldots, n-r_k$ in various branches, then we give a corresponding $\alpha_0$ such that for all $\alpha \geq \alpha_0$, $\alpha^n \geq \alpha^{n-r_1} + \alpha^{n-r_2} + \ldots + \alpha^{n-r_k}$. Having these $\alpha_0$’s for each of the cases below would thus give us that the overall complexity of the algorithm is at most $O(p\text{oly}(n, |\phi|) \times \alpha_1^n)$, for any $\alpha_1$ larger than any of the $\alpha_0$’s used in the cases.

All of our modifications done via case analysis below would convert similar clauses to similar clauses. Thus, if one starts with $\phi_1 = \phi_2$, then as we proceed with the modifications below, the corresponding clauses in the modified $\phi_1, \phi_2$ would remain similar (or both dropped) in the new (sub)problems created. Thus, $\phi_1, \phi_2$ will always have the same structure.

Our algorithm is given below, followed by the detailed case analysis.

**Algorithm Max Hamming Distance X3SAT:** $\text{MHD}(\phi_1, \phi_2, V, s_1, s_2, P)$

Output: The polynomial $p_{\text{main}} \times \sum_{(\beta_1, \beta_2)} \prod_{x \in V} p_x, \beta_1(x), \beta_2(x)$, where $\beta_1, \beta_2$ range over value assignments to variables in $V$ which are satisfying for the formula $\phi_1$ and $\phi_2$ respectively, and which are consistent with the value assignment in $s_1, s_2$, if any, respectively.

Note: As $\phi_1, \phi_2$ have the same structure, the statements below about two clauses being neighbours, or involving $k$-variables (and other similar questions) have the same answer for both $\phi_1, \phi_2$.

if (some clause cannot be satisfied (for example $(0, 0, 0)$ or $(1, x, \neg x)$)) in $\phi_1$ or $\phi_2$ then

return 0. This is Case 1(i).

else if (for some variable $x \in V$, $s_1(x)$ and $s_2(x)$ are both defined) or $(x$ does not appear in any of the clauses) then
return $\text{MHD}(\phi_1, \phi_2, s_1, s_2, V - \{x\}, P[p_{\text{main}} = p_{\text{main}} \times (\sum_{i,j} p_{x,i,j})])$, where summation is over pairs of $(i, j)$ which are consistent with $(s_1(x), s_2(x))$ (if defined). This is Case 1.(ii).

**else if** (some clause contains at most two different variables in its literals) then
simplify $(\phi_1, \phi_2)$ according to Case 1.(iii) and return the answer from the updated MHD problem.

**else if** (there are two clauses sharing exactly 2 common variables) then
simplify $(\phi_1, \phi_2)$ according to Case 1.(iv) and return the answer from the updated MHD problem.

**else if** (there is a variable appearing in at least 4 dissimilar clauses) then
branch on this variable and do follow-up linking of the variables according to Case 1.(v), return the sum of the answers obtained from the subproblems.

**else if** (there is a clause with at least four dissimilar neighbours and there is a small set $I$ of variables which are semiisolated by a small set $J$ of variables and conditions prescribed in Case 1.(vi) below hold; we use this only if $|I| \leq 10, |J| \leq 3$) then
branch on all variables except one in $J$ and simplify according to Case 1.(vi) and return the sum of the answers obtained from the subproblems.

**else if** (there is a clause with at least 4 dissimilar neighbouring clauses) then
branch on up to three variables and do follow-up linking according to Case 1.(vii) and return the sum of the answers from the subproblems.

**else**
In this case all the clauses have at most three dissimilar neighbours, no variable appears in more than 3 dissimilar clauses and each clause has exactly three variables and no two dissimilar clauses share two or more variables.

As described in Case 2 below, one can branch on some variables and after simplification, have two sets of clauses in $\phi_1$ ($\phi_2$) which have no common variables. Furthermore, as the clauses do not satisfy the preconditions for Case 1, they again fall in Case 2, and we can repeatedly branch/simplify the formulas until the number of variables/clauses become small enough to use brute force.

**end if**

### 3.1 Case 1

This case applies when either some clause is not satisfiable irrespective of the values of the variables (case (i)) or some variable in $V$’s value has already been determined for both $\phi_1, \phi_2$ (case (ii)) or some clauses in $\phi_1$ (and thus $\phi_2$) use only one or two variables (case (iii)), or two dissimilar clauses have two common variables (case (iv)), or some variable appears in four dissimilar clauses (case (v)) or some clause has four dissimilar clauses as neighbours (which is divided into two subcases (vi) and (vii) below for ease of analysis).

The subcases here are in order of priority. So (i) has higher priority than (ii) and (ii) has higher priority than (iii) and so on.

(i) If there is a clause which cannot be satisfied (for example the clauses $(0, 0, 0)$ or $(1, 1, x)$ or $(1, x, \neg x)$) whatever the assignment of values to the variables consistent with $s_1, s_2$ in either $\phi_1$ or $\phi_2$ respectively, then $\text{MHD}(\phi_1, \phi_2, s_1, s_2, V, P) = 0$.

(ii) If a variable $x \in V$ is determined in both $\phi_1, \phi_2$ (i.e., $s_1(x)$ and $s_2(x)$ are defined), or variable $x$ does not appear in any of the clauses, then do the simplification: update $p_{\text{main}}$ to $p_{\text{main}} \times (\sum_{i,j} p_{x,i,j})$, where $i, j$ range over value assignments to $x$ in $\phi_1, \phi_2$ which are consistent with $(s_1(x), s_2(x))$ (if defined) respectively. That is, answer returned in this case is $\text{MHD}(\phi_1[x = s_1(x)], \phi_2[x = s_2(x)], s_1, s_2, V - \{x\}, P[p_{\text{main}} = p_{\text{main}} \times (\sum_{i,j} p_{x,i,j})])$, where the summation is over $i, j$ consistent with $s_1(x), s_2(x)$, if defined.
(iii) If there is a clause which contains only one variable. Then, either the value of the variable is determined (for example when the clause is of the form \((x, \neg x, \neg x)\) or \((x)\), for some literal \(x\), which is satisfiable only via \(x = 1\), or the clause is unsatisfiable (for example when it is of the form \((x, x)\) or \((x, x, x)\) — in which case we have that \(MHD(\phi_1, \phi_2, s_1, s_2, V, P) = 0\) or it does not matter what the value of the variable is for the clause to be satisfied (for example, when the clause is \((x, \neg x)\)). Thus, we can drop the clause and note down the value of the variable in the corresponding \(s_i\) if it is determined (if this is in conflict with the variable having been earlier determined in \(s_i\), then \(MHD(\phi_1, \phi_2, \ldots ) = 0\)). Note that \(x\) may be determined in only one of \(\phi_1, \phi_2\), thus we do not update the \(x\) appearing in any of the remaining clauses of \(\phi_1, \phi_2\) to maintain that the clauses of \(\phi_1, \phi_2\) are similar.

If there is a clause which contains literals involving exactly two variables, \(x\) and \(y\), then \(x\) and \(y\) can be linked, either as \(x = y\) or \(x = \neg y\), as we must have exactly one literal in the clause which is true for any satisfying assignment. Thus, we can replace all usage of \(y \text{ by } x\) (or \(\neg x\)) in both \(\phi_1, \phi_2\), drop the variable \(y\) from \(V\) and correspondingly, update, for \(i, j \in \{0, 1\}, p_{x,i,j} \text{ to } p_{x,i,j} \times p_{y,i',j'}, \text{ based on the linking of values } i \text{ for } x \text{ in } \phi_1 \text{ for } x \text{ in } \phi_2 \text{ respectively to value } i' \text{ for } y \text{ in } \phi_1 \text{ for } y \text{ in } \phi_2 \text{ respectively}.

Here, in case value of \(y\) is determined in \(s_1, s_2\), then the value of \(x\) is correspondingly determined — and in case it is in conflict with an earlier determination then \(MHD(\phi_1, \phi_2, \ldots ) = 0\).

So for below assume no clause has literals involving at most two variables.

(iv) Two clauses share two of the three variables in the literals:

Suppose the clauses in \(\phi_1\) are \((x, y, w)\) and \((x', y', z)\), where \(x, x'\) (similarly, \(y, y'\)) are literals over same variable.

If \(x = x', y = y', \text{ then we have } w = z;\)

If \(x = \neg x', y = \neg y', \text{ then we must have } w = z = 0;\)

If \(x = x', y = \neg y', \text{ then we must have } x = 0 \text{ and } w = \neg z; \text{ (case of } x = \neg x' \text{ and } y = y' \text{ is symmetrical).}\)

In all the four cases, we have that \(w\) is linked to \(z\) and thus, \(z\) can be replaced using \(w\) in both \(\phi_1, \phi_2\), with corresponding update of \(p_{w,i,j}\) by \(p_{w,i,j} \times p_{y,i',j'}\), where \(i', j'\) are obtained from \(i, j\) based on the linking in \(\phi_1, \phi_2\) respectively. Here, in case value of \(z\) is determined in \(s_1, s_2\), then the value of \(w\) is correspondingly determined — and in case it is in conflict with an earlier determination then \(MHD(\phi_1, \phi_2, \ldots ) = 0\).

(v) A variable \(x\) appears in at least four dissimilar clauses.

By Cases 1(iii) and 1(iv), these four clauses use, beside \(x\), variables \((y_1, z_1), (y_2, z_2), (y_3, z_3), (y_4, z_4)\) respectively, which are all different from each other. We branch based on \(x\) having values for \((\phi_1, \phi_2)\): \((0, 0), (0, 1), (1, 0)\) and \((1, 1)\). Then, in each of the four clauses involving \(x\), we link the remaining \(y_i\) and \(z_i\). Formulas \(\phi_1, \phi_2\) and \(s_1, s_2, V, P\) are correspondingly updated (that is, \(x\) is dropped from \(V\), \(p_{main}\) is updated to \(p_{main} \times p_{x,i,j}\) based on the branch \((i, j)\), and the linking of the variables is done as in Case 1(iii)).

Note that for each branch, we thus remove the variable \(x\), and one of the other variables in each of the four clauses. Thus we can remove a total of 5 variables for each subproblem based on the branching for \(x\).

(vi) Though technically we need this case only when some clause has four neighbours (see case (vii) and Proposition 3), the simplification can be done in other cases also.

There exists \((I, J), I \cup J \subseteq V\), such that \(|I| \leq 10, |J| \leq 3\) and \((I, J)\) is semiisolated in \(\phi_1\) (and thus in \(\phi_2\) too) and one of the following cases hold.

1. \(j = 1 \text{ and } i \geq 1\): Suppose \(J = \{x\}\). In this case, we can simplify the formulas \(\phi_1, \phi_2\) to remove variables from \(I\) as follows:

   Let \(W = \{\text{value vectors } (\beta_1, \beta_2) \text{ with domain } I \cup \{x\} : \beta_i \text{ is consistent with } s_i \text{ and all clauses involving variables } I \cup \{x\} \text{ in } \phi_i \text{ are satisfied by } \beta_i\}\).
Let \( W_{i,j} = \{ (\beta_1, \beta_2) \in W : \beta_1(x) = i \land \beta_2(x) = j \} \).

Let \( p_{x,i,j} = p_{x,i,j} \times (\sum_{(\beta_1, \beta_2) \in W_{i,j}} \prod_{v \in I} p_v(\beta_1(v), \beta_2(v))). \)

Let \( V = V - I. \)

Remove from \( \phi_1 \) and \( \phi_2 \) all clauses containing variables found in \( I. \) If \( x \) occurs in any clause after the modification, then answer returned is \( \text{MHD}(\phi_1, \phi_2, s_1, s_2, V, P), \)

where the parameters are modified as above.

IF \( x \) does not occur in any clause after above modification, then, let \( p_{\text{main}} = p_{\text{main}} \times \sum_{i,j} p_{x,i,j}, \) where summation is over values \((i, j)\) for \( x \) which are consistent with \((s_1(x), s_2(x))\) if defined. \( V = V - \{x\} \) and the answer returned is \( \text{MHD}(\phi_1, \phi_2, s_1, s_2, V, P), \)

where the parameters are modified as above.

Here note that \( j = 0 \) case can be similarly handled.

2. \( J = \{w, x\} \) and \( i \geq 3, \) where \( x \) appears in some clause \( C \) involving a variable not in \( I \cup J. \)

In this case, we will branch on \( x \) and then using the technique of (vi).1 remove variables from \( I \) and then also link the two variables different from \( x \) in \( C. \) That is, for each \((i,j) \in \{(0,0),(0,1),(1,0),(1,1)\}, \) that is consistent with \((s_1(x), s_2(x))\) subproblem \((\phi_{1,i,j}, \phi_{2,i,j}, s_{1,i,j}, s_{2,i,j}, V_{i,j}, P_{i,j})\) is formed as follows:

(a) Set values of \( x \) in \( \phi_1 \) and \( \phi_2 \) as \( i \) and \( j \) respectively, updating correspondingly \( p_{\text{main}} \) to \( p_{\text{main}} \times p_{x,i,j} \) and drop \( x \) from the variables \( V. \)

(b) Eliminate \( I \) from the subproblem by using the method in (vi).1 (as \( w \) is the only element of corresponding \( J \) in the subproblem).

(c) Link the two variables in the clause \( C \) which are different from \( x. \)

The answer returned by MHD is the sum of the answers of each of the four subproblems.

Note that in each of the four (or less) subproblems, besides \( x \) and members of \( I, \) one linked variable in \( C \) is removed. Thus, in total at least 5 variables get eliminated in each subproblem.

3. \( j = 3 \) and \( i \geq 4 \) and there is a clause which contains at least two variables \( v, w \) from \( J \) and another variable from \( I \) (say the clause is \((v', w', e)\)), where \( v', w' \) are literals involving \( v, w)\); furthermore \( v, w \) appear in clauses involving variables not from \( I: \) In this case we will branch on the variables \( v, w, e \) (consistent with assignments in \( s_1, s_2 \) to these variables if any), and simplify each of the subproblems in a way similar to (vi).2 above. Note that exactly one of \((v', w', e')\) is 1: giving 9 branches based on the three choice for each of \( \phi_1 \) and \( \phi_2. \) The answer returned by MHD is the sum of the answers of each of the (upto) nine subproblems.

Note that apart from the 4 elements of \( I \) and \( v, w, \) for the clauses using variables not from \( I, \) we have two clauses involving \( v \) and \( w. \) The other variables in each of these clauses can be linked up. Thus, in total for each of the subproblems at least 8 variables are eliminated.

(vii) There exists a clause with 4 dissimilar neighbours and none of the above cases apply.

Proposition 4 below argues that there is a clause \((x, y, z)\) (in \( \phi_1 \) and thus in \( \phi_2) \) with at least four neighbours so that further clauses according to one of the following five situations exist (up to renaming of variables):

1. \((x', a, b), (x'', c, d), (y', a', c'), (y'', c', e');\)
2. \((x', a, b), (x'', c, d), (y', e, c'), (y'', f, c');\)
3. \((x', a, b), (x'', c, d), (y', a', c'), (z', e, c');\)
4. \((x', a, b), (x'', c, d), (y', e, c'), (z', f, c');\)
5. \((x', a, b), (x'', c, d), (y', a', c'), (z', c', e').\)

where primed versions of the literals use the same variable as unprimed version (though they may be negated) and \( a, b, c, d, e, f, x, y, z \) are literals involving distinct variables.
Proposition 4. If cases 1.(i) to 1.(vi) above do not apply and if there is a clause with at least four dissimilar neighbours then there is also a clause with neighbours as outlined in (vii).

Proof. Below primed versions of variables denote a literal involving the same variable — though it may be negated version. Given a clause \((x, y, z)\) with at least four dissimilar neighbours, without loss of generality assume that \(x, y, z\) are not negated in this clause (otherwise, we can just interchange them with their negated versions). We let \(x\) denote a variable which is in at least two further dissimilar clauses. In the light of Cases 1.(iii), 1.(iv) not applying, these clauses have new variables \(a, b, c, d\), say \((x', a, b)\) and \((x'', c, d)\) (again without loss of generality, \(a, b, c, d\) are not negated). In light of Case 1.(v) not applying, variable \(x\) is used in no further clause.

If two new variables \(e, f\), different from \(a, b, c, d, x, y, z\) appear in some clauses involving \(x, y, z\) then there are two clauses of the form (A) \((y', b, c)\) and \((y'/z', f, c)\), or (B) \((y', c, f)\) and \((y'/z', a', c)\) (note that in case (B), both \(a, b\) cannot appear in the clause as case 1.(iv) did not apply). Thus, 1.(vii).2 or 1.(vii).4 (in case (A)) or 1.(vii).1 or 1.(vii).3 (in case (B)) apply.

Now, assume that at most one other variable \(e\), appears in any clause involving \(x, y, z\) besides \(a, b, c, d\). Without loss of generality suppose the third neighbour of \((x, y, z)\) was \((y', a', c)\), where \(\cdot\) involves variable \(c\) or \(e\) (it cannot involve \(b\) or \(z\) as Case 1.(iv) did not apply).

Now, if \(a\) or \(b\) appears in a further outside clause involving a variable other than \(x, y, z\) then \(x', a, b\) has neighbours \((x, y, z)\), \((x'', c, d)\), \((a', y', c'/c')\), \((a''/b', f, c)\) and thus 1.(vii).1, 1.(vii).2, 1.(vii).3 or 1.(vii).4 apply (with interchanging of names of \(y\) with \(a\) and \(z\) with \(b\)). If none of \(a\) or \(b\) appears in a further outside clause involving a variable other than \(x, y, z, a, b, c, d, e\), then one of the cases of 1.(vi) applies with \(I \cup J\) being \(\{x, y, z, a, b, c, d\}\) or \(\{x, y, z, z, b, c, d, e\}\) (based on whether \(e\) appears with any of \(x, y, z\) or not in some clause), and \(J \subseteq \{c, d, e\}\) of the variables which appear in clauses not involving \(\{x, y, z, a, b, c, d, e\}\). Here note that in case \(J = \{c, d, e\}\), then the side condition of 1.(vi).3 is satisfied using clause \((c, d, x'')\).

3.2 Case 2

This case applies when all clauses have exactly three variables, no two clauses have exactly two variables in common, no variable appears in more than three dissimilar clauses and dissimilar clauses have at most three dissimilar neighbours.

As our operations on similar clauses leaves them similar, for ease of proof writing, we will consider similar clauses in any of the formulas as “one” clause when counting below.

Suppose there are \(m\) dissimilar clauses involving \(n\) variables. First note that for this case, \(m \leq 2n/3\). To see this, suppose we distribute the weight 1 of each variable equally
Proposition 5. For some $\epsilon_m$ which goes to 0 as $m$ goes to $\infty$, the following holds.

Suppose in $\phi_1$ (and thus $\phi_2$) there are $n$ variables and $m$ dissimilar clauses each having three literals involving three distinct variables, such that each clause has at most three dissimilar neighbours and each variable appears in at most three dissimilar clauses, and no two dissimilar clauses have two common variables.

Then, we can select $k \leq m(1/6 + \epsilon_m)$ variables, such that branching on all possible values for all of these variables, and then doing simplification based on repeated use of Case 1.(i) to 1.(iv) gives two groups of clauses, each having three literals, where the two groups have no common variables, and

(a) each clause in each group has at most three dissimilar neighbours,
(b) each variable appears in at most three dissimilar clauses,
(c) no pair of dissimilar clauses have two common variables,
(d) the number of dissimilar clauses in each group is at most $(m - k + 2)/2$.

Proof. To prove the proposition, consider each dissimilar clause as a vertex, with edge connecting two dissimilar clauses if they have a common variable. Using the bisection width result [10, 11, 15], one can partition the dissimilar clauses into two groups (differing by at most one in cardinality) such that there exist at most $k \leq (1/6 + \epsilon_m) \times m$ edges between the two groups, that is there are at most $(1/6 + \epsilon_m) \times m$ common variables between the two groups of clauses. One can assume without loss of generality that at most one clause has all its neighbours on the other side. This holds as if there are two dissimilar clauses, say one in each half, which have all their neighbours on the other side, then we can switch these two clauses to the other side and decrease the size of the cut. On the other hand, if both these clauses (say $A$ and $B$) belong to the same side, then we can switch $A$ to the other side, and switch the side of one of $B$’s neighbours — this also decreases the size of the cut.

To see that the properties mentioned ((a), (b) and (c)) are preserved, suppose in a clause $(x, y, z)$, we branch on $x$ and thus link $y$ with $z$; here we assume without loss of generality that $x, y, z$ are all positive literals. Note that as $(x, y, z)$ has at most three neighbours, one of which contains $x$, there can be at most two other neighbours of the clause $(x, y, z)$ which contain $y$ or $z$.

First suppose $y$ (respectively $z$) does not appear in any other clause. Without loss of generality assume that $y$ gets dropped and replaced by $z$ or $\neg z$ based on the linking. Then dropping the clause $(x, y, z)$ and replacing $y$ by $z$ does not increase the number of dissimilar clauses that $z$ appears in, nor does it increase the number of neighbours of these clauses as there is no change in variable name in any clause which is not dropped.

Next suppose both $y$ and $z$ appear in exactly one other dissimilar clause, say $(y', a, b)$ and $(z', c, d)$, where $y'$ and $z'$ are literals involving $y$ and $z$ respectively. In that case, linking $y$ and $z$ (and replacing $z$ by $y$), makes these two clauses neighbours (if not already so) — which is compensated by the dropping of the neighbour $(x, y, z)$; the number of clauses in which $y$ appears remains two. In case these two clauses were already neighbours (say $a = c$ or $\neg c$), then due to application of Case 1.(iv), $b$ and $d$ get linked, clauses $(y, a, b)$ and $(z, c, d)$ thus become similar (resulting in decrease in the neighbour by one for these clauses) and the above analysis can then be recursively applied for linking $b$ with $d$.

Now considering the edges (and corresponding common variable for the edge) in the cut, and branching on all these variables (while being consistent with $s_1$ and $s_2$) and then doing simplification as in Cases 1(i) to 1(iv), we have that each partition is left with at most $(m + 1 - (k - 1))/2$ dissimilar clauses. This holds as, by our assumption above, except maybe
for one clause, all dissimilar clauses have at most two neighbours on the other side. Thus, by linking the remaining variables for each of the clauses involved in the cut, we can remove \((k - 1)/2\) dissimilar clauses on each side using Case 1(iii).

Thus, one can recursively apply the above modifications in Case 2 to each of the two groups of clauses, one after other, until all the variables have been assigned the values or linked to other variables (where the leaf cases occur when the number of dissimilar clauses is small enough to use brute force assigning values to all of the variables).

Now we count how many variables need to be branched for Case 2 in total if one starts with \(m\) clauses involving \(n\) variables. The worst case happens when \(k = (1/6 + \epsilon_m)n\) and the total number of variables which need to be branched on is \(m(1 + 5/12 + 5^2/(12^2) + \ldots) + (1/6 + \epsilon)\), where one can take \(\epsilon\) as small as desired for corresponding large enough \(m\). Thus the number of variables branching would be \(m(2/7 + 2\epsilon/7)\) for \(n(4/21 + 2\epsilon/21)\).

As branching on each variable gives at most 4 children, the number of leaves (and thus complexity of the algorithm based on Case 2) is bounded by \(4^{\alpha r/21 + o(r)}\).

### 3.3 Overall Complexity of the Algorithm

Note that modifications in each of the above cases takes polynomial time in the original formula \(\phi\).

Visualize the running of the above algorithm as a search tree, where the root of the tree is labeled as the starting problem \(\text{MHD}(\phi, \phi, V = X, s_1 = \emptyset, s_2 = \emptyset, P)\), with \(P\) having \(p_{\text{main}} = 1, p_{\text{x,y,j}} = q_{\text{x,y,j}}\).

At any node, if a simplification case applies, then the node has only one child with the corresponding updated parameters. If a branching case applies, then the node has children corresponding to the parameters in the branching.

As the work done at each node is polynomial in the length of \(\phi\), the overall time complexity of the algorithm is \(\text{poly}(n, |\phi|) \times (\text{number of leaves in the above search tree})\).

We thus analyze the number of possible leaves the search tree would generate.

Suppose \(T(r)\) denotes the number of leaves rooted at a node \(\text{MHD}(..., V, \ldots)\), where \(V\) has \(r\) variables.

Case 1.(i) to Case 1.(iv) and Case 1.(vi).1 do not involve any branching.

If Case 1.(v) is applied to a MHD problem involving \(r\) variables, then it creates at most four subproblems, each having at most \(r-5\) variables. Thus, the number of leaves generated in this case is bounded by \(4T(r-5)\). Note that \(T(r) = O(\alpha r)\), for \(\alpha \geq \alpha_0 = 1.3196\) satisfies the constraints of this equation.

If Case 1.(vi).2 is applied to a MHD problem involving \(r\) variables, then it creates at most 4 subproblems each involving at most \(r-5\) variables. Thus, the number of leaves generated in this case is bounded by \(4T(r-5)\). Note that \(T(r) = O(\alpha r)\), for \(\alpha \geq \alpha_0 = 1.3196\) satisfies the constraints of this equation.

If Case 1.(vi).3 is applied to a MHD problem involving \(r\) variables, then it creates at most 9 subproblems each involving at most \(r-8\) variables. Thus, the number of leaves generated in this case is bounded by \(9T(r-8)\). Note that any \(T(r) = O(\alpha r)\), for \(\alpha \geq \alpha_0 = 1.3162\) satisfies the constraints of this equation.

If Case 1.(vii) is applied to a MHD problem involving \(r\) variables, then it creates at most 6 subproblems, one involving at most \(r-4\) variables and the other involving at most \(r-7\) variables. Thus, the number of leaves generated in this case is bounded by \(T(r-4) + 5T(r-7)\). Note that any \(T(r) = O(\alpha r)\), for \(\alpha \geq \alpha_0 = 1.3298\) satisfies the constraints of this equation.

If Case 2 is applied to a MHD problem of \(r\) variables, then it creates a search tree which contains at most \(O(4^{\alpha r/21 + o(r)})\) leaves. Note that any \(T(r) = O(\alpha r)\), for \(\alpha \geq \alpha_0 = 1.3023\) satisfies the constraints of this equation.
Thus, the formula $T(r) = O(1.3298^n)$ bounds the number of leaves generated in each of the cases above, for large enough $r$. Thus, we have the theorem:

**Theorem 6.** Given a 3XSAT formula $\phi$, one can find in time $O(poly(n, |\phi|) \times 1.3298^n)$ the maximum hamming distance between any two satisfying assignments for $\phi$.

## 4 Comparing with Reductions to Known Methods

An early approach of computing maximal Hamming distances between solutions was an algorithm which (a) enumerates all the solutions on one side and then (b) finds for each solution of (a) the most distant solution on the other side. This method exploited that for (b), one can use a method of maximising a variable weighted X3SAT which by Porschens and Plagge \[16\] takes approximately time $1.1192^n$; one cannot say at least, as they did not prove a lower bound for this but only an upper bound. The performance of this algorithmic idea mainly depends on the number of solutions in (a). If one considers $n = 2n' + 1$ clauses $(x_1, x_{2m}, x_{2m+1})$ with $m = 1, \ldots, n'$, then there are $1 + 2^n$ solutions which is, for most $n$, at least $1.414^n$. So the overall runtime is approximately $1.5825^n$.

In the following, we want to lay out more in detail why referring to standard methods like Max 2-CSP or the above mentioned algorithm does not give better bounds than the algorithm provided in the current paper. The following three remarks, the first for the special case and the next two for the full problem, give some estimated bounds on these type of approaches. The goal is to try to give a fair comparison based on a reasonable way of using this approach.

**Remark 7.** Assume that one has to compute the maximum Hamming distance for an X3SAT formula which meets the specification of Case 2 in the algorithm. Then one could formalise this as a Max 2-CSP problem as follows: One makes a graph of all clauses where a clause is considered to be a set of 3 nodes. Each node takes a colour from $\{1, 2, 3\}^2$ where the coordinate 1, 2, 3 indicates whether the first, second or third literal is made true in the clause, as it is X3SAT, exactly one of these three options applies. Furthermore, the two coordinates in the pair refer to the first and the second solution of the X3SAT problem. If two clauses share a variable, they are neighbours; for neighbours one makes the hard constraint that the shared variables in the two nodes are given consistent values. The weak constraint is the Hamming distance of the two solutions, here one evaluates for each variable the Hamming distance of the two solutions in the node is a number from 0 to 3 which reflects the Hamming distance of the variables in the solution which occur in this node first. The hard constraints have for each pair the weight $n + 1$ (greater than the sum of all weak constraints) in the case that the hard constraint is satisfied and 0 in the case that the hard constraint is not satisfied. Now, as the underlying graph has degree at most 3, the algorithm of Gaspers and Sorkin \[11\] provides the bound of $9^{\frac{3n}{2} + o(n)}$ where $m$ is the number of nodes in the graph, that is, the number of clauses in the given formula. This number $m$ is at most $\frac{2}{3} \times n$ due to the special form of the graph. Thus the overall time complexity is $9^{\frac{3n}{2} + o(n)}$ and this is contained in $O(1.3404^n)$. Thus the complexity of the naïve invocation of Max 2-CSP in an important special case would give a bound worse than the algorithm for solving the full problem in this paper; so it pays off to make a specialised algorithm for the problem of determining the maximum Hamming distance of two solutions of a X3SAT instance.

**Remark 8.** One could also try to solve the full problem with the invocation of the Max 2-CSP algorithm. Gaspers and Sorkin \[11\] provide the bound of $9^{nh/50}$ for a instance with $h$ edges in the underlying graph (which optimises a sum over the value functions along the edges of the graph plus a further sum over the value functions of the nodes). Again one would take the nodes as clauses and for every variable occurring in $k + 1$ clauses, one would make $k$ edges, connecting the first and second clause where it occurs, the second and third
clause where it occurs, . . . , the k-th and k + 1-st clause where it occurs. Along these edges, one puts the hard constraint that the corresponding values of the variable are the same and they carry the weight n + 1; along the nodes one puts the weak constraint equal to the Hamming distances of the value-vectors of those variables in the two solutions which occur in this clause but do not appear in any earlier clause. The maximum constraint value can, if there is a solution, only be taken by a pair of solutions which satisfies all the hard constraints and its value is n + 1 times the number of hard constraints plus the maximum Hamming distance.

Let r be the average number of clauses in which a variable occurs. Now the time bound for the PSPACE algorithm for this problem is $g^{r/50 \times (r n - n + o(n))}$ in dependence of r and n. For r = 3.0 this is contained in $O(2.2057^n)$, for r = 2.3 this is contained in $O(1.6723^n)$ and for r = 2.0 this is contained in $O(1.4852^n)$. For the case that one does not want to specify an average degree, the time bound can be estimated by $O(g^{r/50 \times (3m - n) + o(m)})$ every clause has at most 3 edges connecting to later clauses and for each variable which occurs the last time in a clause, there is no edge connecting to a further later clause, thus the $-n$ term.

In the case that one uses exponential space algorithms, there are slightly better bounds supplied by Scott and Sorkin \cite{17} which are, for the above case, $g^{(13/75 + o(1)) \times (r - 1) \times n}$ giving $O(1.4636^n)$ for r = 2.0, $O(1.6407^n)$ for r = 2.3 and $O(2.1420^n)$ for r = 3.0. These algorithms are, even for the moderate value r = 3.0, not competitive with Dahllöf's original algorithm \cite{3, 4} which solves the maximal Hamming distance even for XSAT and not only X3SAT. Thus it pays off to make a specialised tailor-made algorithm rather than to plug in a known general method for the case of Max Hamming Distance X3SAT.

\begin{remark}
One might ask why the above approach takes the clauses as vertices of the CSP graph and not the variables. The main reason is that published results which give the CSP complexity in terms of vertices are, mainly, just the paper of Williams \cite{19}: He shows that one can solve the Max 2-CSP constraint problem in time $O^*(1.732^n)$; however, this result is for binary variables only. Williams' method does not allow that a variable takes four values, as otherwise we could compress pairs of variables into one variable and bring the result is for binary variables only. Williams' method does not allow that a variable takes four values, as otherwise we could compress pairs of variables into one variable and bring down the complexity to $O^*(1.732^{n/2})$ and then do the same thing again. For that reason, to cast Max Hamming X3SAT into this framework, we would have to go for an $O^*(1.732^{n/2})$ algorithm, which is much slower than Dahllöf's algorithm \cite{3, 4} of $O(1.8348^n)$.

A better way would be to use Max weighted 2SAT with 3n variables instead of n. Wahlström \cite{18} provides for this an algorithm in time $O^*(1.2377^n)$; this algorithm would then be placed on instances with 3n variables which corresponds to $O(1.8961^n)$ which is slightly above Dahllöf's algorithm. For this, recall that maximum weighted 2SAT assigns to every variable a weight and searches for a solution of the 2SAT formula which maximises the weight. The translation is as follows: We let ($x_1, \ldots, x_n$) and ($y_1, \ldots, y_n$) represent the two solutions of X3SAT problem; ($z_1, \ldots, z_n$) is an auxiliary vector with the constraint that $z_k$ can only be 1 when $x_k = 0$ and $y_k = 1$; this is achieved by putting the clauses $\neg z_k \lor \neg x_k$ and $\neg z_k \lor y_k$ into the 2SAT formula. Furthermore, for each X3SAT clause, we put into the 2SAT formula the conditions that no two literals in the clause are satisfied at the same time, that is, for a clause $x_i \lor x_j \lor \neg x_k$ in the X3SAT instance the corresponding 2SAT clauses would be $\neg x_i \lor \neg x_j \lor \neg x_k$ and $\neg x_i \lor x_k$. Similarly we put the 2SAT clauses for the y-variables. Now let $i_k$ be the number of clauses containing $x_k$ in the X3SAT instance and $j_k$ be the number of clauses containing $\neg x_k$ in the X3SAT instance. The weights are as follows:

1. $x_k = 1$ has weight $(n + 1) \cdot i_k + 1$;
2. $x_k = 0$ has weight $(n + 1) \cdot j_k$;
3. $y_k = 1$ has weight $(n + 1) \cdot i_k$;
4. $y_k = 0$ has weight $(n + 1) \cdot j_k + 1$;
5. $z_k = 1$ has weight 2;
6. $z_k = 0$ has weight 0.
Note that the Hamming distance is not a linear function and therefore we need the variable \( z_k \) to correct errors when computing the Hamming distance from weights on \( x_k \) and \( y_k \); this correction is good when the number of \( z_k = 1 \) is maximised, given assignments of \( x_1, \ldots, x_n \) and \( y_1, \ldots, y_n \) which solve the X3SAT problem. Now the overall maximal weight of two solutions \( x, y \) and \( z \) being maximised is

\[
2 \cdot m \cdot (n+1) + n + H D(x, y),
\]

where \( m \) is the number of clauses in the X3SAT instance. The reason for this is that every satisfied clause for \( x \) contributes one time \( n+1 \) and every satisfied clause for \( y \) also contributes one time \( n+1 \) to the sum. Additionally, the part of the weights which is not determined by X3SAT clauses is, for each \( k \), equal to \( x_k + 1 - y_k + 2z_k \); the part \( x_k + 1 - y_k \) is 1 if \( x_k \) and \( y_k \) are the same; 2 if \( x_k = 1 \) and \( y_k = 0 \) or 0 if \( x_k = 0 \) and \( y_k = 1 \). Note that \( z_k \) can be 1 iff \( x_k = 0 \) and \( y_k = 1 \). Therefore, by choosing \( z_k \) suitably, if \( x_k \) and \( y_k \) differ then the sum of the parts of the weight of \( x_k, y_k, z_k \) not linked to coding X3SAT clauses is 2 else this sum is 1. Thus taking \( x_k, y_k \) and the maximised \( z_k \) into account, the additional weight of \( x_k + 1 - y_k + 2z_k \) is 1 + \( H D(x_k, y_k) \). Taking this for all \( n \) variables into account gives \( n + H D(x, y) \).

Alternatively, one could use the approach of Porschen and Plagge [16] to solve variable-weighted X3SAT in time \( O(2^{0.16255n}) \). However, X3SAT formulas are not very suitable for coding the Hamming distance and therefore three additional variables are needed for each pair of \( x_k \) and \( y_k \), giving a total of \( 5n \) variables. This blown up problem then has the performance of \( O(1.7566^n) \), so the overall performance is better than Dahllöf’s algorithm but worse than the one of Fu, Zhou and Yin [12].

5 Conclusion and Future Work

In this paper, we considered a branching algorithm to compute the Max Hamming Distance X3SAT in \( O(1.3298^n) \) time. Our novelty lies in the preservation of structure at both sides of the formula while we branch.

Our method is faster than the naïve invocation of the Max 2-CSP algorithm (see the discussion in the previous section). Even if one assumes that every clause has only three neighbours (as in Case 2, but now from the start), the usage of the Max 2-CSP algorithm results in a run-time of \( 9^{2/15}n + o(n) \) which is contained in \( O(1.3404^n) \). Without this assumption, the naïve invocation of the Max 2-CSP algorithm is much worse. Also other invocations of known methods do not give good timebounds.

Our time bound of \( O(1.3298^n) \) is achieved by using simple analysis to analyse our branching rules. Our algorithm uses only polynomial space during its computations. This can be seen from the fact that the recursive calls at the branchings are independent and can be sequentialised; each calling instance therefore needs only to store the local data: thus each node of the call tree uses only \( h(n) \) space for some polynomial \( h \). The depth of the tree is at most \( n \) as each branching reduces the variables by 1; thus the overall space is at most \( h(n) \times n \) space.

Furthermore, as we determine the number of pairs of solutions with Hamming distance \( k \) for \( k = 0, 1, \ldots, n \), where \( n \) is the number of variables, one might ask whether this comes with every good algorithm for free or whether there are faster algorithms in the case that one computes merely the maximum Hamming distance of two solutions.
