ABSTRACT

We present timing and spectral analysis of Rossi X-ray Timing Explorer-Proportional Counter Array observations of SMC X-1 between 1996 January and 2003 December. From observations around 1996 August 30 with a time-span of ~6 d, we obtain a precise timing solution for the source and resolve the eccentricity as 0.00089(6). We find an orbital decay rate of \( \dot{P}_{\text{orb}}/P_{\text{orb}} = -3.402(7) \times 10^{-6} \, \text{yr}^{-1} \) which is close to the previous results. Using our timing analysis and the previous studies, we construct a ~30 yr long pulse period history of the source. We show that frequency derivative shows long- (i.e. more than a few years) and short-term (i.e. order of days) fluctuations. From the spectral analysis, we found that all spectral parameters except Hydrogen column density showed no significant variation with time and X-ray flux. Hydrogen column density is found to be higher as X-ray flux gets lower. This may be due to the increase in soft absorption when the pulsar is partially obscured as in Her X-1 or may just be an artefact of the tail of a soft excess in energy spectrum.

Key words: accretion, accretion discs – stars: neutron – pulsars: individual: SMC X-1 – X-rays: binaries.

1 INTRODUCTION

The high-mass X-ray binary (HMXB) system SMC X-1/Sk 160 consists of a neutron star with a mass of ~1.06 M\(_{\odot}\) (van der Meer et al. 2007) and a spin period of 0.71 s (Lucke et al. 1976), accreting from the B0I star Sk 160 with a mass of ~17.2 M\(_{\odot}\) (Reynolds et al. 1993). Orbital period of the system is ~3.9 d (Schreier et al. 1972). The system has been observed with several observatories since it was discovered during a rocket flight (Price et al. 1971). It is the only discovered HMXB with a supergiant companion in SMC so far (Galache et al. 2008).

From the pulse timing studies, the source was observed to be spinning up since it was discovered (Wojdowski, Clark George & Levine Alan 1998). Levine et al. (1993) and Wojdowski et al. (1998) found an orbital period decay in the system with \( \dot{P}_{\text{orb}}/P_{\text{orb}} \) of ~3.4 × 10^{-6} yr^{-1}.

SMC X-1 also exhibits super-orbital X-ray flux variations like the 35-d cycle of Her X-1 (Gruber & Rothschild 1984). Average super-orbital period of the source is ~55 d (Wojdowski et al. 1998; Trowbridge, Nowak & Wilms 2007). The super-orbital X-ray flux variations of SMC X-1 are thought to be due to the precession of a warped accretion disc (Wojdowski et al. 1998).

In this paper, we present timing and spectral analysis of Rossi X-ray Timing Explorer (RXTE) observations of SMC X-1 between 1996 January and 2003 December. In the next section, we give brief information about instruments and observations. In Section 3, we present the results of timing analysis, including pulse period history and timing solution of the source. In Section 4, X-ray spectral analysis of the source is presented.

2 INSTRUMENTS AND OBSERVATIONS

We analysed data from Proportional Counter Array (PCA) on board RXTE (Jahoda et al. 1996) of SMC X-1 between 1996 January and 2003 December (MJD 500 93–529 88).

The RXTE-PCA consists of an array of five Proportional Counters (PCU) operating in the 2–60 keV energy range, with a total effective area of approximately 7000 cm\(^2\) and a field of view of ~1° full width at half-maximum. Data obtained from top xenon layers (L1 and R1) of PCUs were used to maximize signal over noise (S/N) in the 3–20 keV energy band. For the observations after 2000 May, for which the propane layer for PCU0 was lost, data obtained from PCU0 were not used in the spectral analysis.

Out of 167 total pointings, we excluded X-ray eclipses (due to low count statistics) and used data obtained from ~130 pointings with a total exposure of ~250 ks for the timing analysis. Other than the public observations, the principal investigators of these observations are S. Eikenberry, W. Heindl, D. Chakrabarty, G. W. Clark and J. Deeter. During the observations between 1998 October 16 and 1998 November 24, with an exposure of ~23 ks, the data were contaminated due to the outburst of the nearby transient X-ray pulsar XTEJ0111.2-7317 (Chakrabarty et al. 1998). We did not use these observations in the X-ray spectral analysis. In order to obtain

*E-mail: inam@baskent.edu.tr (SCİ); elif@astroa.physics.metu.edu.tr (AB)
the timing solution of the source, we used observations with the proposal number 10139 covering a time-span of about 6 d. These observations are more suitable than other observations to obtain the timing solution, since they are the only set of observations that continuously cover near two orbital periods.

3 TIMING ANALYSIS

For the timing analysis, we generated light curves (3–20 keV) with 0.035-s timing resolution using Good Xenon data. These light curves were background-corrected with a 16-s binned background light curve constructed using background estimator models from the RXTE team (URL: ftp://legacy.gsfc.nasa.gov/xte/calib_data/pca_bkgd/). The resulting light curves were corrected to the barycentre of the Solar system. A template pulse profile from each RXTE observation was constructed by folding the data on the period which had the greatest power in the periodogram. Pulse arrival times were found by cross-correlating the pulse profiles obtained from ∼200 s long segments with the template pulse profile. Both the template and cross-correlated pulse profiles consisted of 20 phase bins. Cross-correlation was performed by using the harmonic representation of pulse profiles (Deeter & Boynton 1985). In order to obtain pulse arrival times, the pulse profiles were expressed in terms of harmonic series and cross-correlated with the template pulse profile.

3.1 Timing solution

Initially, we found pulse arrival times obtained from a series of observations with a time-span of ∼6 d around MJD 503 24.7. These pulse arrival times can be fitted to an expression to obtain timing solution (Deeter, Boynton & Pravdo 1981). We firstly assumed a

| Parameters                  | Model (this work) |
|-----------------------------|-------------------|
| Timing epoch (MJD)          | 503 26.623 56961(9) |
| ν (Hz)                      | 1.413630801(4)    |
| ν(10⁻¹¹ Hz s⁻¹)             | 3.279(5)          |
| Orbital Period (d)          | 3.892200909(4)    |
| a/c sin I (lt-s)            | 53.4876(9)        |

| Pobs/Ptrue (10⁻⁶ yr⁻¹)      | −3.402(7)         |
| Eccentricity                | 0.00089(6)        |
| w (longitude of periastron) | 166(12)           |

Figure 1. Arrival times (pulsation cycles) (top panel) and residuals after fitting arrival times to a circular (middle panel) and elliptical orbital model (lower panel) obtained from the observations with a time-span of about 6 d around 1996 August 30.
3.2 Pulse period history

For the other observations between MJD 500 93 and MJD 529 88 (each having ∼1–2 ks exposure), we roughly obtained pulse periods using the periodogram and then refined these periods by the use of a linear fit to the arrival times. Errors were estimated using the scattering of arrival time values (i.e. errors were related to the errors of the linear coefficient of the fit). These periods were corrected for the binary motion of the pulsar using the orbital parameters listed.
Table 3. Pulse frequency history of SMC X-1.

$^1$ errors indicated in the parenthesis give the value for each pulse period in 1σ.

in Table 1. We present the whole pulse period history of the source in Table 3 and Fig. 3 including our results. From Fig. 3, it is evident that the source spins up continuously between MJD ∼400.00 and ∼530.00 with a varying spin-up rate. In Table 4, average spin-up rate values of the source are listed.

4 SPECTRAL ANALYSIS

The same 130 RXTE-PCA observations used for the timing study were also used for the spectral analysis except those between 1998 October 16 and November 24 which were contaminated due to the outburst of the nearby transient X-ray pulsar XTEJ0111.2-7317 (Chakrabarty et al. 1998). We used the Standard-2 mode data, which provide 128 channel spectra at 16 s time resolution. Spectrum, background and response matrix files were created using FTOOLS 6.3 data analysis software. We used background-subtracted spectra in our analysis. Energy channels corresponding to the 3–25 keV energy range were used to fit the spectra. We ignored photon energies lower than 3 keV and higher than 25 keV and 1 per cent systematic error was added to the errors (see Wilms et al. 1999; Coburn et al. 2000).

To fit the spectra, we used a power-law model with a high-energy cut-off and a Gaussian component peaking at 6.7 keV (Angelini, Stella & White 1991). We also tried to add a partial covering absorption component (Neilsen, Hickox & Vrtilek 2004), but adding this model component did not improve the fit.

Table 5 shows best-fitting parameters of the spectral model for two sample observations. In general, we found that power-law index, high-energy cut-off and e-fold energy does not show variations with time, orbital phase and X-ray flux within the errors. We found that Hydrogen column density gets higher when X-ray flux is lower (see Fig. 4).

5 DISCUSSION

In this paper, we presented timing and spectral analysis of RXTE-PCA observations of SMC X-1 with a time-span of about 8 yr. From timing analysis, we revised timing solution of the source and resolved an eccentricity value. We also confirmed the orbital decay reported before. Our timing analysis helped us to construct a ∼30 yr long pulse period history of the source (see Fig. 3). From the spectral analysis, we found that all spectral parameters except Hydrogen column density showed no significant variation with time and X-ray flux.

Fig. 1 demonstrates that the eccentric orbit model is a better fit compared to the circular orbital model. The timing solution of the source revealed that the binary orbit has an eccentricity of 0.00089(6). Wojdowski et al. (1998) had found a circular orbital solution and Levine et al. (1993) had only found an upper limit of 0.00004 for eccentricity. Our present value is more than 20 times greater than the upper limit found by Levine et al. (1993). This significant eccentricity value should be verified using future monitoring observations.

From timing analysis, we obtained a new orbital epoch of SMC X-1 from RXTE observations. Using this new epoch and previous results (Wojdowski et al. 1998), we found that there is an orbital decay with $P_{\text{orbit}}/P_{\text{orb}}$ of $-3.402(7) \times 10^{-6}$ yr$^{-1}$. This value is similar to the values found by Wojdowski et al. (1998) and Levine et al. (1993). Levine et al. (1993) proposed that the major cause of change in the orbital period is tidal interactions as for the case in Cen X-3 (Kelley et al. 1983) and LMC X-4 (Levine, Rappaport & Zojchowski 2000). SMC X-1 is unlike Her X-1 for which the mass accretion was thought to be primarily related to the orbital period decay (Deeter et al. 1991).

From Fig. 3, it is seen that SMC X-1 spins up continuously for about 30 yr. We found that average long-term spin-up rate of the source between MJD 500 93.048 and 529 87.640 (whole time-span of our analysis) is $2.65343816(7) \times 10^{-11}$ Hz s$^{-1}$.

Spin-up rate of a source with a persistent accretion disc can be expressed as

$$\dot{v} \approx 2.2 \times 10^{-12} \mu_{50}^{2/7} m_{\text{m}}^{-3/7} R_{\text{n}}^{6/7} I_{\text{IS}}^{-1} F_{\text{57}}^{6/7} \text{Hz s}^{-1},$$

where $\dot{v}$ is first time derivative of the spin frequency, $\mu_{50}$ is the magnetic moment of the neutron star in units of $10^{30}$ G cm$^3$, $m_{\text{m}}$ is the mass of the neutron star in units of solar mass, $R_{\text{n}}$ is the radius of the neutron star in units of cm, $I_{\text{IS}}$ is the moment of inertia of the neutron star in terms of $10^{45}$ g cm$^2$ and $L_{57}$ is the luminosity of the neutron star in units of $10^{37}$ erg s$^{-1}$ (Ghosh & Lamb 1979). Using a distance value of 61 kpc (Keller & Wood 2006) and a flux of $1.2 \times 10^{-9}$ erg cm$^{-2}$s$^{-1}$ (see Fig. 4), luminosity of SMC X-1 is $\sim 5.5 \times 10^{40}$ erg s$^{-1}$. Assuming magnetic moment of $10^{30}$ G cm$^3$, mass of $1.4 M_{\odot}$, radius of $10^{6}$ cm, moment of inertia of $10^{45}$ g cm$^2$, we find $\dot{v}$ to be $\sim 5.9 \times 10^{-11}$ Hz s$^{-1}$. This value is of the order of the observed spin-up rate value of the source.
Inam, A. Baykal and E. Beklen

Figure 3. (top) and (middle) Pulse frequency history and residuals of SMC X-1 after a linear fit obtained from five different intervals listed in Table 4. (bottom) Frequency derivative history. Dashed lines in top and middle panels and horizontal error bars in the bottom panel indicate time intervals in which linear fits were performed. The last (rightmost) interval almost consists of pulse frequency values obtained from our analysis.

Table 4. Long-term spin-up rate values of SMC X-1.

| Interval (MJD–MJD) | Spin-up rate (10^{-11} Hz s^{-1}) |
|-------------------|----------------------------------|
| 410 00–428 50     | 3.59(48)                         |
| 429 50–461 00     | 2.3718(15)                       |
| 469 00–478 00     | 2.2491438(1)                     |
| 484 50–492 00     | 1.9528(38)                       |
| 500 93–529 88     | 2.65343816(7)                    |

From Fig. 3 and Table 4, it is evident that the long-term spin-up rate of SMC X-1 varies within a factor of 2. From equation (3), this variation may – in principle – be related to a change in X-ray luminosity of the source. However, previous X-ray observations of the source were performed by different X-ray observatories and/or in different energy bands. These observations are sparsely distributed and average X-ray flux of these observations are not likely to represent an average X-ray flux for the intervals for which the pulse frequency derivatives were found. Moreover, X-ray flux variations are also affected by the super-orbital cycle, period of which is not as stable as that of Her X-1 (Clarkson et al. 2003). Therefore, it is not possible to test whether variation in long-term spin-up rate is related to a change in X-ray luminosity or not.

From Table 1, spin-up rate obtained from ~6 d long observation around MJD 503 24.7 is 3.279(5) × 10^{-11} Hz s^{-1}. This is about 20 per cent greater than the long-term spin-up rate between MJD 500 93 and 529 88. Assuming that the pulse frequency variations can be explained in terms of random walk model in pulse frequency (Baykal & Ogelman 1993), one can express the pulse frequency derivative variations as ∆Ω^1/2 = S√t, where S is the noise strength and t is the time interval at which the pulse frequency derivatives are observed. Therefore, it is natural to observe high pulse frequency derivative fluctuations at shorter time-scales. It is important to note that we refined pulse period values fitting arrival times each obtained from ~200 s long intervals; therefore, we had to have at least a few arrival times to obtain spin period accurately. So, our shortest time-scale to obtain pulse periods is of the order of a single RXTE observation which is ~1–2 ks long.

From the spectral analysis, we found that all of the spectral parameters except Hydrogen column density did not vary significantly. Hydrogen column density was found to be higher as X-ray flux gets lower. Increase in Hydrogen column density with a decrease in X-ray flux is also observed in Her X-1 (Inam & Baykal 2005) and may be due to the fact that soft absorption becomes stronger whenever there is a partial obscuration of the neutron star due to the X-ray eclipses and warping of the accretion disc. The increase in Hydrogen column density may also be an artefact of the simple absorbed power-law model. Paul et al. (2002) showed that SMC X-1 has soft excess especially for energies \( \lesssim 3 \) keV. Although we used photon energies greater than 3 keV in our analysis, tail of a soft spectral component may affect low energies in our analysis and as a result we might have misidentified corresponding changes in energy spectrum as variations in Hydrogen column density parameter.
