Salinity stress, which induces both ionic and osmotic damage, impairs plant growth and causes severe reductions in crop yield. Plants are equipped with defense responses against salinity stress such as regulation of ion transport including Na\(^+\) and K\(^+\), accumulation of compatible solutes and stress-related gene expression. The initial Ca\(^{2+}\) influx mediated by plasma membrane ion channels has been suggested to be crucial for the adaptive signaling. NADPH oxidase (Nox)-mediated production of reactive oxygen species (ROS) has also been suggested to play crucial roles in regulating adaptation to salinity stress in several plant species including halophytes. Respiratory burst oxidase homolog (Rboh) proteins show the ROS-producing Nox activity, which are synergistically activated by the binding of Ca\(^{2+}\) to EF-hand motifs as well as Ca\(^{2+}\)-dependent phosphorylation. We herein review molecular identity, structural features and roles of the Ca\(^{2+}\)-permeable channels involved in early salinity and osmotic signaling, and comparatively discuss the interrelationships among spatiotemporal dynamic changes in cytosolic concentrations of free Ca\(^{2+}\), Rboh-mediated ROS production, and downstream signaling events during salinity adaptation in planta.

Keywords: Ca\(^{2+}\)-permeable channels, NADPH oxidases (Noxs), osmotic stress, reactive oxygen species (ROS), salinity stress

Introduction

Soil salinity impairs plant growth and development and is an important factor limiting crop productivity and yield worldwide (Rengasamy, 2006). Salinity stress reduces water potential, thereby preventing water uptake by roots and provoking a set of responses similar to those of a water deficit. Thus, by causing osmotic stress, salinity provokes the stomatal limitation of photosynthesis, loss of turgor, enhanced photorespiration, and excess production of ROS (Chaves et al., 2009). The ionic component of salinity stress is attributed to the direct toxic effects of Na\(^+\) and imbalances in the homeostasis of other ions such as K\(^+\) and Ca\(^{2+}\) (Munns and Tester, 2008).
To mount an effective response to cope with salinity stress, land plants have developed the ability to sense both osmotic stress and Na⁺ (Deinlein et al., 2014). Plants exhibit a rapid increase in the cytosolic Ca²⁺ concentration within seconds of being exposed to NaCl or mannitol (Knight et al., 1997). The Ca²⁺ rise originated within the roots (Tracy et al., 2008) is propagated systemically (Choi et al., 2014), and occurs in several cell types (Kiegle et al., 2000).

Reactive oxygen species such as O₂⁻ (superoxide anion radical), H₂O₂ (hydrogen peroxide), and OH⁻ (hydroxyl radical) are highly toxic substances produced through aerobic respiration and photosynthesis that oxidize various biomolecules such as DNA, proteins and lipids, and disrupt the cell redox state. Therefore, plants have developed various systems to scavenge ROS (Choudhury et al., 2013). Direct exposure of plant tissues to H₂O₂ activates antioxidant enzymes as well as the expression of the corresponding genes (Mylona et al., 2007). ROS are also enzymatically produced and act as signaling molecules in plant responses to abiotic and/or biotic stresses (Kärkönen and Kuchitsu, 2015).

Respiratory burst oxidase homologs has been identified as ROS-producing Noxs that generate O₂⁻ by oxidizing NADPH and transferring an electron to oxygen (Sumimoto, 2008). Noxs are rapidly activated in response to various stimuli to induce ROS production and are involved in the regulation of a wide range of physiological functions in plants (Marino et al., 2012). Rbohs play central roles in the Ca²⁺-ROS signaling network triggered by their phosphorylation during stress adaptation (Takeda et al., 2008; Kimura et al., 2012; Gilroy et al., 2014).

We here review molecular mechanisms and roles of PM Ca²⁺-permeable channels as putative osmosensors and enzymatic ROS production involved in early salinity and osmotic responses, and discuss the interrelationships among dynamic changes in [Ca²⁺]cyt. ROS production, downstream signaling events during salinity sensing and adaptation in plants including halophytes.

**Candidates for Plant Ca²⁺-Permeable MS Channels as Osmosensors**

Mechanical stimuli, such as touch, bending, and barriers for growth as well as osmotic potential changes, all elicit rapid and transient increases in [Ca²⁺]cyt. Expression of cellular Ca²⁺-binding regulatory proteins including CaM and CML are induced by mechanical stimuli (Braam and Davis, 1990). Early responses to salinity stress reflect turgor changes and involve Ca²⁺-mediated signaling (Donaldson et al., 2004). PM Ca²⁺-permeable MS channels are suggested to sense salinity stress-triggered osmotic potential change. The following protein families are suggested as putative plant PM Ca²⁺-permeable MS channels as osmosensors.

**OSCA1**

OSCA1 was recently identified as a novel putative PM hyper-osmolality-gated Ca²⁺-permeable channel in guard cells and roots of *Arabidopsis* (Yuan et al., 2014). OSCA1 comprises nine transmembrane α-helices, but shows no significant similarity to known ion channels. Electrophysiological analyses of OSCA1 expressed in HEK293 cells showed its hyper-osmolality-gated Ca²⁺-permeable channel activity (Yuan et al., 2014). In osca1, early osmotic signaling events in guard cells were impaired and downstream adaptation responses against osmotic stress were attenuated (Yuan et al., 2014).

**MCA Family**

The yeast Mid1 protein shows MS channel activity when expressed in mammalian cells (Kanzaki et al., 1999). MCAs were identified in *Arabidopsis* based on their ability to complement the yeast mutant mid1 (Nakagawa et al., 2007). MCAs comprise at least one transmembrane domain and contain an EF hand, but show no significant similarity to known ion channels. All MCAs are localized to the PM and mediate Ca²⁺ uptake, with the N-terminal and EF hand regions being necessary structures for transport. MCAs are present in all land plants, including ferns and mosses, but not in algae, animals, protists, or fungi, suggesting that the function of MCAs is fundamental to land plants (Kurusu et al., 2013).

Ca²⁺ current induced by trinitrophenol, a potent compound to generate membrane distortion to activate MS channels, is enhanced in the MCA1-overexpressing cells (Nakagawa et al., 2007), and MCA1 and MCA2 expressed in *Xenopus* oocytes showed MS cation channel activity (Furuuchi et al., 2012). Touch response in the primary root is impaired in mca1, while mca2 showed lower root Ca²⁺ uptake (Nakagawa et al., 2007; Yamanaka et al., 2010), suggesting that MCA1 and MCA2 play different physiological roles. Hypo-osmotic shock-induced PM Ca²⁺ influx and ROS production are partially impaired in OsMCA1-suppressed rice cultured cells (Kurusu et al., 2012a). Tobacco MCA homologs are localized at the Hechtian strand that connects PM and cell wall (Kurusu et al., 2012b). These findings suggest that MCAs are involved in hypo-osmotic stress-induced PM Ca²⁺ influx (Kurusu et al., 2013). MCA1 and MCA2 form a tetramer (Nakano et al., 2011; Shigematsu et al., 2014), suggesting that MCA proteins may function as a tetramer to form a Ca²⁺-permeable pore.

**MSL Family and Others**

Genome-wide screening to search for plant MS channels homologous to eukaryotic and prokaryotic MS channels identified the MSL protein family (Haswell et al., 2011). MSLs are present in land plants, and electrophysiological studies suggest that MSL9 and MSL10 permeate Cl⁻ rather than Ca²⁺ (Haswell et al., 2008). It remains unknown whether any of MSLs are involved in the mechanical stimuli-induced Ca²⁺ influx as Ca²⁺-permeable channels.

Piezo proteins in mouse and *Drosophila* are also pore-forming subunits of MS channels and respond to mechanical stimuli. Many eukaryotic species including plants but not yeast and bacteria have a single Piezo protein (Coste et al., 2010). Functional roles of plant Piezo protein have not yet been reported.
An *Arabidopsis* histidine kinase HK1 may share a similar function with yeast Sln1 as an osmosensor (Urao et al., 1999; Wohlbach et al., 2008). It is of interest to determine whether any of these putative MS channels or osmosensors interacts with each other physically or functionally to monitor mechanical stimuli under salinity stress.

**Plant Signaling Networks Involving \( Ca^{2+} \) and ROS under Salinity Stress**

**Physiological Roles of Rboh/Nox in Early Salinity Responses in *Arabidopsis***

Reactive oxygen species are highly toxic substances that oxidize various biomolecules. Generation of \( \cdot OH \) has significant implications to cell metabolism and causes lipid peroxidation (Apel and Hirt, 2004). \( K^+ \) deficiency causes an increase in \( O_2^- \) production by Rboh/Nox in root cells, and enhanced activation of antioxidant enzymes under salinity stress involves cytosolic \( K^+ \) retention, suggesting that optimizing the \( K^+ \) nutritional status may reduce the toxic effect of ROS by regulating Nox activity, and is essential for plant performance against salinity (Shabala and Pottosin, 2014).

Exposure to salinity activates the SOS pathway, leading to \( Ca^{2+} \)-dependent activation of SOS1, a PM \( Na^+ \)/H\(^+\) exchanger that enables adaptation through \( Na^+ \) efflux (Shi et al., 2000; Chung et al., 2008). Expression of *SOS1* is induced under salinity stress, which requires activation of the *Ca^{2+}*-sensor *SOS3/CBL4* (calcineurin B-like 4) (Shi et al., 2000). Nox-mediated ROS production stabilizes *SOS1* transcripts (Chung et al., 2008). Growth of better-adapted secondary roots is impaired in *sos1* (Huh et al., 2002) and involves \( O_2^- \) production, possibly by Rboh/Nox (Roach and Kranner, 2011).

*Arabidopsis* contains 10 Nox genes, *RbohA-J*, which exhibit different patterns of expression and in response to environmental factors (Marino et al., 2012). Expression of *RbohD* and *RbohF* are highly induced under salinity stress (Ma et al., 2012). An *RbohF* mutant showed strong \( Na^+ \) hypersensitivity in its shoots and lacked ROS accumulation in its vasculature (Jiang et al., 2013), suggesting that *RbohF* plays a role in the regulation of xylem loading of \( Na^+ \) to protect leaves from salinity stress in *Arabidopsis*. ROS production by Rboh/Nox is also suggested to be coordinated by signaling pathways involving phospholipid and actin in salinity stress responses, and is required for heme oxidase-mediated salt acclimation signaling (Xie et al., 2011).

The Interrelationships between *Ca^{2+}* Influx and Rboh/Nox-Mediated ROS Production in Early Salinity Responses

Plant Rbohs have two N-terminal EF-hand motifs. A heterologous expression system based on HEK293T cells is effective to quantitatively evaluate (Ogasawara et al., 2008) and reconstitute the ROS-producing activity of Rbohs (Drrerup et al., 2013; Kimura et al., 2013). Rbohs are basically synergistically activated by the \( Ca^{2+} \)-binding to the EF-hand motifs and phosphorylation (Ogasawara et al., 2008). Protein phosphorylation is a prerequisite for the \( Ca^{2+} \)-dependent activation of Rbohs (Kimura et al., 2012). *Arabidopsis* CIPK26, binds to RbohF in *plant* (Kimura et al., 2013) and in the presence of PM-localized *Ca^{2+}*-sensor proteins CBL1/CBL9, CIPK26 enhances the activity of RbohF (Drrerup et al., 2013). Rbohs are phosphorylated and activated by two families of \( Ca^{2+} \)-dependent protein kinases (CBL-CIPK complexes and CDPKs; Kobayashi et al., 2007; Drrerup et al., 2013; Dubiella et al., 2013), and two families of \( Ca^{2+} \)-independent protein kinases (RLCKs and SnRK2s; Sirichandra et al., 2009; Kadota et al., 2014).

Salinity-induced elevation of \( [Ca^{2+}]_{cyt}\) corresponds to PM \( Ca^{2+} \) influx as well as \( Ca^{2+} \) release from intracellular \( Ca^{2+} \) stores, and plays important roles in ROS signaling and salt tolerance (Shabala and Newman, 2000; Kader and Lindberg, 2010). Salinity-induced \( Ca^{2+} \) influx currents were markedly suppressed in the *rbohd/F* double mutant in *Arabidopsis*, implicating the roles of RbohD and RbohF in salt-stimulated \( [Ca^{2+}]_{cyt} \) rise (Ma et al., 2012).

Plant annexins have been reported to form \( Ca^{2+} \)-permeable channels in planar lipid bilayers (Laohavisit and Davies, 2011). *Arabidopsis* ATANN1 is localized at the PM and responsible for root epidermal PM \( Ca^{2+} \)-permeable conductance, which is activated by extracellular \( OH^- \) (Lee et al., 2004; Laohavisit et al., 2012). High concentration of NaCl promotes extracellular formation of \( OH^- \) (Demidchik et al., 2010) and accumulation of ATANN1 in membranes (Lee et al., 2004), and promotes secondary root formation (Huh et al., 2002). ATANN1-mediated \( Ca^{2+} \) influx through the PM depends on extracellular \( Ca^{2+} \) and ROS, and the *atann1* mutant shows reduced secondary root formation and reduced activation of NaCl-induced transcription under salinity stress conditions (Laohavisit et al., 2013), suggesting a role of ATANN1 in root cell adaptation to salinity in *Arabidopsis*.

Salinity-induced \( Na^+ \) accumulation in the cytosol triggers \( [Ca^{2+}]_{cyt} \) elevation, leading to activation of Rboh/Nox (Lecourieux et al., 2006) and apoplastic \( H_2O_2 \) accumulation. By interacting with transition metal such as Fe in the cell wall, \( H_2O_2 \) forms \( OH^- \) (Kuchitsu et al., 1995; Rodrigo-Moreno et al., 2013). \( OH^- \) directly activates both outward-rectifying depolarization-activating \( K^+ \) channels (GORKs) and \( K^+ \)-permeable NSCCs, resulting in \( K^+ \) leakage from roots (Shabala and Pottosin, 2014). The absolute concentration of \( K^+ \) is essential to confer salinity stress tolerance, and the loss of \( K^+ \) is suggested to play a primary role in the activation of caspase-like proteases and PCD (Shabala, 2009).
Salinity also induces accumulation of polyamines. Polyamines could generate ROS as a substrate of amine oxidases in the apoplast (Kärkönen and Kuchitsu, 2015). Both OH· and polyamines may provoke a substantial remodeling of PM conductance of cations and anions and affect Ca2+ signaling in plants including halophytes (Pottosin et al., 2014). Crosstalk between ROS and polyamines in the regulation of PM ion transport may reveal a novel function of ROS production as signaling molecules during salinity adaptation.

A Ca2+-ROS Signaling Network in Osmotic Responses in Roots under Salinity Stress

Osmotic-shock induces Ca2+ influx followed by ROS production in many cell types in plants. The Ca2+ influx and Nox-mediated ROS production triggered by osmotic shock both require extracellular Ca2+, suggesting that PM Ca2+ influx is a prerequisite for ROS production (Beffagna et al., 2005).

mid1-complementing activities (MCAs), putative PM Ca2+-permeable MS channel components are suggested to play a role in the regulation of mechanical responses via signal transduction pathways dependent on Ca2+ and ROS (Kurusu et al., 2013). The overexpression of OsMCA1 enhances Rboh/Nox-mediated ROS production in rice cultured cells (Kurusu et al., 2012a). MCA1 and ROS produced by RbohD and/or RbohF may play roles in the modulation of osmosensitive metabolic changes (Wormit et al., 2012). Overexpression of MCAs enhances the expression of touch-inducible gene TCH3/CML12 encoding a CML in Arabidopsis (Nakagawa et al., 2007).

Apoplastic ROS production plays a key role in regulating cell wall metabolism, e.g., cross-linking of polysaccharides and glycoproteins to control cell wall rigidity (O’Brien et al., 2012; Kärkönen and Kuchitsu, 2015). H2O2 is also transported to the cytosol by PM aquaporins (Dynowski et al., 2008) to modify the cysteine residues of target proteins, thereby promoting redox signaling (Spoel and Loake, 2011).

FIGURE 1 | A possible Ca2+-ROS signaling network involved in osmotic responses under salinity stress in root cells. Salinity stress causes osmotic shock to trigger the activation of PM MS Ca2+-permeable channels and Ca2+ influx. Elevated [Ca2+]cyt leads to activation of various Ca2+ sensor proteins including CaMts, CMLs, CBLs, CDPKs as well as the ROS-producing enzyme, Noxs/Rbohs that are synergistically activated by Ca2+ binding and phosphorylation by Ca2+-dependent protein kinases such as CDPKs and CBL-CIPK complexes. Elevated apoplastic ROS activates ROS-activated PM Ca2+-permeable channels to trigger further Ca2+ influx, while Ca2+-permeable endomembrane channels/transporters may also be activated to sustain further Ca2+ mobilization. Elevated [Ca2+]cyt may trigger downstream events such as activation of SOS1 and NHX1, Na+/H+ exchangers that transport cytosolic Na+, regulation of xylem loading of Na+, induction of osmolytes and osmo-protective proteins, and the retention of cytosolic ion balance. Ca2+-dependent protein kinases activated by elevated [Ca2+]cyt mediate downstream events including expression of genes encoding proteins such as SOS1, antioxidant enzymes, osmolytes-biosynthetic enzymes as well as CaMs as signal amplifiers. Elevated [Ca2+]cyt is reverted by the orchestrated action of active transporters such as Ca2+ exchangers and Ca2+-ATPases at the PM and tonoplast. H2O2 is transported to the cytosol by PM aquaporins to modify the cysteine residues of target proteins, thereby promoting redox signaling to regulate gene expression. Broken arrows indicate hypothetical links. ACA, autoinhibited Ca2+-ATPase; PA, polyamine; PAO, polyamine oxidase.
These findings suggest the following initial PM signaling mechanism in response to osmo-stimulation under salinity stress (Figure 1): Salinity stress causes osmotic shock to trigger the activation of PM MS Ca\(^{2+}\)-permeable channels and Ca\(^{2+}\) influx. Elevated cytosolic Ca\(^{2+}\) leads to the activation of various Ca\(^{2+}\) sensor proteins including CaMs, CMLs, CBLs, and CDPKs. Rbohs are synergistically activated by Ca\(^{2+}\)-binding to the EF-hand motifs and phosphorylation to produce ROS. Elevated cytosolic Ca\(^{2+}\) and apoplastic ROS may also activate not only ROS-activated PM Ca\(^{2+}\)-permeable channels including annexins but also as-yet- unidentified Ca\(^{2+}\)-permeable channels/transporters localized at the endomembranes to sustain further Ca\(^{2+}\) mobilization. The signaling network dependent on Ca\(^{2+}\) and ROS may play a crucial role in regulating downstream events such as the Ca\(^{2+}\)-dependent activation of Na\(^{+}\)/H\(^{+}\) exchangers, SOS1 and NHX1 (Reguera et al., 2014), Na\(^{+}\) efflux from the cytosol, regulation of xylem loading of Na\(^{+}\) (de Boer and Wegner, 1997), Na\(^{+}\) exclusion from leaves (Sunarpi et al., 2005), induction of osmolytes and osmo-protective proteins, and the retention of cytosolic ion balance. Once this signaling is over, elevated [Ca\(^{2+}\)]\(_{cyt}\) would be reverted by the orchestrated action of Ca\(^{2+}\) exchangers and Ca\(^{2+}\)-ATPases at the PM and tonoplast (reviewed in Bose et al., 2011).

Calcium-dependent protein kinases (Boudsocq and Sheen, 2013) and CBL-CIPK complexes (Weinl and Kudla, 2009) are suggested to transduce the osmotic signal to regulate downstream posttranslational modification and gene transcription. Furthermore, transcription factors such as calmodulin-binding transcription activators (CAMTAs; Pandey et al., 2013) are suggested to be directly activated by Ca\(^{2+}\)/CaM. Interestingly, a recent comparative expression study in glycophytes and halophytes revealed that the induction of Ca\(^{2+}\)/CaM-like proteins such as CDPKs are clearly enhanced in halophytes against salinity stress (Xu et al., 2013). Such Ca\(^{2+}\)-binding proteins may play roles as important ‘amplifier’ of initial PM Ca\(^{2+}\) influx and Rboh-mediated ROS production in salinity stress signaling. Ca\(^{2+}\) signaling also plays a critical role in salinity stress-triggered systemic signaling. A cation channel TPC1 is reported to be involved in the propagation of salinity stress-triggered systemic Ca\(^{2+}\) wave in roots, and may also be contributing to whole-plant resistance to salinity stress in Arabidopsis (Choi et al., 2014). Ca\(^{2+}\)-ROS waves involving TPC1 may elicit systemic molecular responses in target organs and contribute to whole-plant stress tolerance (Choi et al., 2014; Gilroy et al., 2014).

Hydrogen peroxide transported from the apoplast to the cytosol by PM aquaporins may also interact with O\(_2\)\(^{•-}\) generated in the mitochondria under salinity stress to generate OH\(^{•}\) in the cytosol by Fenton reaction, which could activate NSCCs from the cytosolic site (Rodrigo-Moreno et al., 2013). As NSCCs are permeable to Na\(^{+}\), Ca\(^{2+}\), and K\(^{+}\), this activation may enhance Na\(^{+}\) uptake and K\(^{+}\) loss, further causing the cytosolic K\(^{+}\)/Na\(^{+}\) imbalance. The resultant K\(^{+}\) loss from the cell may induce activation of caspase-like proteases and leading to PCD. Moreover, OH\(^{•}\)-induced activation of NSCCs may further boost Ca\(^{2+}\) uptake, providing an additional positive feedback loop.

### Possible Function of Initial ROS Production and Downstream Signaling Events during Stress Adaptation in Halophytes

The salt tolerance of halophytes is typically examined after long-term exposure to different NaCl concentrations (Tada et al., 2014). However, plant responses to salinity may be determined by rapid perception of salt shock that occurs within hours (Ellouzi et al., 2011; Wang et al., 2012).

Recent comparative studies of three Brassicaceae species, namely two halophytes, Cakile maritima and Thellungiella saltuginea, and a glycophyte, Arabidopsis thaliana, demonstrated that both osmotic potential changes and enhanced transient ROS production occurred in the halophyte roots within hours of exposure to NaCl, and subsequently enhanced the activation of antioxidant defenses as well as expression of transcription factors in the leaves and roots under long-term salinity stress. In contrast, the ROS accumulation continued in the glycophyte, Arabidopsis, during the entire observation period (Ellouzi et al., 2014), indicating that osmotic shock triggered by salinity stress may activate the initial production of ROS, and this phase is the basis of all functional changes leading to a second phase to activate defense mechanisms (Choudhury et al., 2013). The early production of H\(_2\)O\(_2\) by RbohD and RbohF is suggested to be required for salinity-induced antioxidant defense responses in Arabidopsis under short-term stress treatments (Ben Rejeb et al., 2015). Interestingly, the Nox activity decreased under salinity stress in a glycophyte (B. juncea), while it was unaffected in a halophyte (S. portulacastrum) (Srivastava et al., 2015). These findings suggest that early production of low levels of H\(_2\)O\(_2\) acts as an acclimation signal to trigger a preconditioning response by inducing antioxidant enzyme activities in order to efficiently cope with the subsequent production of ROS and lipid peroxidation, thereby preventing or minimizing salinity stress-derived injuries in several halophytes. Regulatory mechanisms of Nox-mediated ROS production in the salinity stress response have not yet been examined genetically in halophytes. Future studies on Rbohs/Noxs in various plant species including halophytes may reveal a novel function of ROS production as signaling molecules during salinity adaptation.

Halophytes do not always need to possess high antioxidant activity because of their higher capacity to prevent ROS generation (Bose et al., 2014). Salt-tolerant species equipped with efficient mechanisms for Na\(^{+}\) exclusion from the cytosol may not require a high level of antioxidant activity. Such exclusion is most probably achieved by the orchestrated action of several complementary mechanisms including SOS1-mediated Na\(^{+}\) exclusion from the cell (Shi et al., 2000), vacuolar Na\(^{+}\) sequestration by tonoplast NHXs (Blumwald, 2000) and efficient control of tonoplast fast (FV) and slow (SV) channels to prevent Na\(^{+}\) back-leak into the cytosol (Bonales-Alatorre et al., 2013a,b).

Although a rapid [Ca\(^{2+}\)]\(_{cyt}\) increase mediated by PM Ca\(^{2+}\)-permeable MS channels and their interacting molecules is a hallmark response to osmotic stress (Monshausen and Gilroy, 2009; Kurusu et al., 2013), Ca\(^{2+}\)-independent osmotic sensory
mechanisms may also play a role. Effectors of ROS and signaling cascades downstream of Rboh need to be elucidated to better understand their roles. The crosstalk of Rboh/Nox-mediated Ca2+-dependent ROS production with other signaling pathways involving ABA, MAPK, and NO as well as jasmonic acid may be important in transcriptional regulation.

In addition, mild salinity stress in the seedling stage induces osmotic priming in Arabidopsis (Sani et al., 2013). Since salinity stress has been shown to affect DNA methylation status of many promoters in soybean (Song et al., 2012), the promoter regions of Rboh in halophytes may have characteristic consensus sequences involved in chromatin modification, and may thus, enhance plant salinity tolerance.
