ABSTRACT

We present the discovery of three faint dwarf galaxies and a globular cluster in the halos of the Andromeda galaxy (M31), found in our MegaCam survey that spans the southern quadrant of M31, from a projected distance of ~50 kpc to ~150 kpc. Though the survey covers 57 sq. degrees, the four satellites lie within 2° of one another. From the tip of the red giant branch, we estimate that the globular cluster lies at a distance of 631 ± 58 kpc from the Milky Way and along with a ~100 kpc projected distance from M31 we derive a total distance of 175 ± 55 kpc from its host, making it the farthest M31 globular cluster known. It also shows the typical characteristics of a bright globular cluster, with a half-light radius of 2.3 ± 0.2 pc and an absolute magnitude in the V band of $M_V = -8.5 ± 0.3$. Isochrone fitting reveals it is dominated by a very old population with a metallicity of [Fe/H] ~ −1.3. The three dwarf galaxies are revealed as overdensities of stars that are aligned along red giant branch tracks in their color-magnitude diagrams. These satellites are all very faint, with absolute magnitudes in the range $-7.3 \lesssim M_{V,0} \lesssim -6.4$, and show strikingly similar characteristics with metallicities of [Fe/H] ~ −1.4 and half-light radii of ~120 ± 45 pc, making these dwarf galaxies two to three times smaller than the smallest previously known satellites of M31. Given their faintness, their distance is difficult to constrain, but we estimate them to be between 740 and 955 kpc which places them well within the virial radius of the host galaxy. The panoramic view of the MegaCam survey can provide an unbiased view of the satellite distribution of the Andromeda galaxy and, extrapolating from its coverage of the halo, we estimate that up to 45 ± 20 satellites brighter than $M_V \sim -6.5$ should be orbiting M31. Hence faint dwarf galaxies cannot alone account for the missing satellites that are predicted by ΛCDM models, unless they reside in dark matter mini-halos that are more massive than the typical mass of $10^7 M_\odot$ currently inferred from their central radial velocity dispersion.

Key words: galaxies: structure – galaxies: dwarf – galaxies: formation – galaxies: individuals (And XI, And XII, And XIII)

1 INTRODUCTION

A generic prediction of Cold Dark Matter (CDM) cosmology is the existence of copious sub-structure in gravitation-
ally collapsed structures such as galaxy clusters, galaxy halos and even dwarf galaxies \cite{klypin1999,moore2000}. On the scale of large spiral galaxies like the Milky Way and the Andromeda galaxy (M31), upwards of 500 dense dwarf galaxy-mass clumps are expected to orbit in the halo. These structures have very dense cores, with a very steep radial profile \cite{navarro1995,moore1999}, which renders them essentially impermeable to Galactic tides. However, more than two orders of magnitude fewer luminous dwarf galaxies have so far been found in the Local Group.

Several studies have investigated the effect of reionization on the early evolution of small structures (e.g. \cite{bullock2000,sommerville2002,tully2002}). Any gas that is not in deep potential wells is lost from the protogalaxies as the first ionizing sources turn on. This “squelching” of star-formation could solve the CDM satellite over-production problem by rendering low-mass galaxies invisible, or at least very dark, depending on the gas fraction that managed to cool to dense molecular form before reionization. Generally, the observed distribution of dwarf satellites can be brought into agreement with CDM if dwarf galaxies reside in large dark matter halos \cite{stoehr2002}, but it opens the possibility that lower mass dwarfs are being missed.

The recent discoveries of faint dwarf galaxies around both the Andromeda galaxy and our Milky Way could be the first step in uncovering such satellites. Andromeda IX (And IX, \cite{zucker2006,chapman2001}), Andromeda X (And X, \cite{zucker2006}), Ursa Major (UMa, \cite{willman2005}), Canes Venatici (CVn, \cite{zucker2006a}), and Boo (\cite{booth2006,booth2006a}) appear to be highly dark matter dominated and could correspond to the dark matter substructures that are found in the CDM models. The discovery of all these faint dwarf galaxies within wide-field surveys (the Sloan Digital Sky Survey and the INT Wide Field Camera survey of the inner halo of M31; \cite{ibata2001,ferguson2002}) revealed the need to conduct systematic surveys of large regions of the halos of the Milky Way or the Andromeda galaxy in order to properly constrain the low luminosity end of their satellite distribution with adequate statistics.

Even though the M31 galaxy is located at 785 ± 25 kpc \cite{mcconnachie2005} from the Sun, surveying the Andromeda galaxy halo has the advantage of requiring to map a much smaller area to have a panoramic view of its halo compared to the Milky Way within which we sit and whose disk and bulge significantly hamper observations at low latitude. Hence we undertook a systematic survey of the outer part of the M31 halo that extends the inner halo survey conducted by our team, which has revealed a flurry of substructures \cite{ibata2001,ferguson2002,mcconnachie2004,ibata2003}. The new survey was conducted with the wide field camera MegaCam mounted on the Canada-France-Hawaii Telescope and spans the whole Southern quadrant of the M31 halo. Covering 57 square degrees, it extends from a projected distance of ~50 to ~150 kpc at the distance of M31.

In this paper, we present the discovery of the three new faint dwarf galaxies that appear in this survey, revealed by an overdensity of stars on the sky that follow red giant branch (RGB) tracks at the distance of M31. The farthest globular cluster in the halo of M31 is also reported. The dataset is presented in section 2 and the characteristics of the four new satellites are derived in section 3 and discussed in section 4. We conclude in section 5. We refer the reader to a companion paper \cite{ibata2006} for the search and analysis of large scale structures in the MegaCam survey.

2 OBSERVATIONS AND REDUCTION

The MegaCam instrument is a wide field camera composed of a mosaic of 36 CCDs that cover a total area of 0.96° × 0.94°. Each CCD is composed of 2048 × 4612 pixels of 0.187 arcseconds. The camera is mounted on the 3.6 m Canada-France-Hawaii Telescope on Mauna Kea, ensuring excellent image quality. Each of the 63 fields of the survey was observed in the g and i bands with an exposure time of 1450 s per filter in seeing better than 0.8. This yielded limiting magnitudes of ~ 25.5 and ~ 24.5 in the g and i bands, respectively.

The raw images were pre-processed by the CFHT team using the Elixir system \cite{elixir} in order to correct for the instrumental signature across the whole mosaic. Then we reduced the data using a version of the CASU pipeline adapted for MegaCam observations to produce catalogues of magnitudes, colors and object morphological classifications. The g and i magnitudes are de-reddened using the $E(B-V)$ values from \cite{schlegel1998}. Comparing the observed RGB stars of the new satellites with isochrones is essential for deriving their parameters. We use the \cite{girardi2000} isochrones for comparison since they are available in the SDSS g and i system. To avoid age-metallicity degeneracy, we choose to use only old isochrones (14 Gyr) as halo globular clusters and the dominant dwarf galaxy stellar populations are generally found to be old (see e.g. \cite{mackey2004} for Galactic halo globular clusters and \cite{grebel2001} for dwarf galaxies). To check the applicability of these isochrones we first compared them to the Andromeda III dwarf galaxy. The color-magnitude diagram (CMD) of stars within 3’ of the center of the dwarf galaxy is shown on the left panel of Figure 1. The \cite{girardi2000} isochrones have been overlaid on the CMD at the distance of the dwarf ($m-M = 24.37$, \cite{mcconnachie2005}) and are in good agreement with the metallicity of And III ([Fe/H] = −1.7, \cite{mcconnachie2005}). In the following, an estimate of the metallicity of each RGB star at the distance of M31 is provided by the ratio of the distances in

Three new faint dwarfs in the outer halo of the Andromeda galaxy

3 FOUR NEW M31 COMPANIONS

The four new M31 companions were discovered directly during a visual inspection of the CMDs and sky maps of the 63 fields of the survey. They correspond to groups of stars that are at the same time clumped on the sky and aligned along a RGB track. An automatic search to detect more diffuse substructures or those that could remain hidden in a denser background population (e.g. in the giant stream that is also present in the survey region) will be presented in a companion paper (Martin et al., in prep). The four satellites described here are all recovered with a high signal-over-noise ratio in the automatic search.

Among the four satellites, one is a bright globular cluster (GC) and three have the characteristics of faint dwarf galaxies. Following the naming convention adopted by Armandroff, Davies & Jacoby (1998) and Armandroff, Jacoby & Davies (1999), we call these And XI, XII and XIII. Surprisingly, they all lie within two degrees of the CMD from this star to the two closest isochrones. Even though this will only be a crude estimation of the metallicity of this star, a more precise determination is not possible given the uncertainties on the distance and age of the stars.

The right panel of Figure 4 shows the CMD of a typical outer halo field of the MegaCam survey. The isochrones are placed at the distance of M31 \((m - M = 24.47; \text{McConnachie et al. } 2005)\) and reveal that the Galactic contamination coming from disk stars at \(2.0 < (g - i)_0 < 3.0, \ i_0 < 23.0\) and halo stars at \(0.2 < (g - i)_0 < 0.8\) and \(i_0 < 22.0\) is mainly avoided, especially for the typical color of the stellar populations found in the new satellites.

Figure 1. Left: CMD of a region of 3' around the Andromeda III dwarf galaxy. Girardi et al. (2004) isochrones have been overlaid for a population of 14.15 Gyr with \([\text{Fe/H}] = -2.3, -1.7, -1.3, -0.7, -0.4, 0.0\) and \(+0.2\) (from left to right) and at the distance of And III \((m - M = 24.37)\). Right: CMD of a one square degree MegaCam field in the outer parts of the M31 halo. The isochrones are also overlaid and correspond to regions that are not significantly contaminated by Galactic disk stars \((2.0 < (g - i)_0 < 3.0, \ i_0 < 23.0)\) and halo stars \((0.2 < (g - i)_0 < 0.8\) and \(i_0 < 22.0)\). The mean uncertainty on the \(i\) magnitude values are shown as a function of magnitude on the left of the panel.

For one another (see Figure 2). The derived parameters of the four objects are summarized in Table 1

3.1 And XI

This satellite is the most luminous of the three new dwarf galaxies found around M31. It is however so faint that the MegaCam image observed in the \(g\) band does not show any visible dwarf, although it does correspond to an overdensity of stars (bottom right panel of Figure 5). The CMD of the region within 3 arcminutes of the central position of the dwarf is constructed in the left panel of Figure 6 and shows a RGB, composed of \(\sim 40\) stars with an implied metallicity of \([\text{Fe/H}] \sim -1.3\). The metallicity distribution of stars with \(i_0 < 24.0\) (top right panel of the same Figure) indeed shows a higher number of stars around the median value of \(-1.3\). Only stars within this peak, that is with \(-1.8 < [\text{Fe/H}] < -0.8\) that populate the RGB (thick histogram) are considered as And XI stars and used to determine the parameters of the dwarf. However, the low number of RGB stars makes these determinations quite uncertain. In particular, the location of the tip of the red giant branch (TRGB), often used to determine the distance of galaxies, is hard to pinpoint among the contaminating stars from the Galactic foreground and the Andromeda halo. The absence of a clear horizontal branch in the MegaCam data conspires

\(^a\) The low number of stars in these dwarfs makes it difficult to determine their distance modulus, which is taken as the one of the M31 galaxy. See also section 4 down below.

\(^b\) The metallicity value for GC is derived from isochrone fitting.

Figure 3. Left: Color-magnitude diagram of the region within 3' of the center of And XI. Isochrones for a 14 Gyr population from Girardi et al. (2000) have been overlaid assuming the distance of M31. The magnitude limit used to determine the parameters of the dwarf \((i_0 < 24.0)\) is shown as the thin dashed line. Most stars are aligned along a RGB with a metallicity of \([Fe/H] \sim −1.3\). Right, top panel: Metallicity distribution of the corresponding stars. The distribution is centered around a median value of −1.3 (arrow) and only stars with −1.8 < [Fe/H] < −0.8 are considered to belong to the dwarf and used to derive its parameters (thick histogram). Right, bottom panel: Distribution on the sky of stars within the And XI metallicity range. They are clearly well clustered within a 3’ radius (the white dashed circle). The background map is obtained by smoothing the star distribution with a 0.5’ Gaussian, revealing a rather smooth and elliptical overdensity despite the low number of stars.

to prevent a proper determination of the distance (even though the group of stars at \((g − i) \sim 0.4\) and \(i_0 \sim 25.0\) could represent such a horizontal branch). Hence, we use the distance of M31 as the distance of And XI \((m − M = 24.47, McConnachie et al. 2005)\) but see section 4 below.

The center of the dwarf, determined as the mean of the stars within 3 arcminutes and with \(−1.8 < [Fe/H] < −0.8\) is \((\alpha, \delta) = (0^h 46^m 20^s, +33^\circ 48^\prime 05^\prime\)). The luminosity profiles of the dwarf in both the g and i bands are constructed from this center by adding the flux contribution of each star, corrected from the background contaminating flux that is determined from stars within an annulus between 4 and 10 arcminutes.

The light profiles become flat within 2 to 4 arcminutes (confirming that there should not be many stars from the dwarf that are missed by the 3’ cut) and yield an average half-light radius of \(r_{1/2} = 0.5 ± 0.1\). The uncertainties are determined from a bootstrap method, randomly re-generating the flux of each star from the flux distribution of And XI stars. Since these uncertainties do not take into account the uncertainty on the background flux or the uncertainties on the metallicity and distance cuts, we double them to yield a more realistic value \(r_{1/2} = 0.5 ± 0.2\). At the distance of M31, this converts to \(r_{1/2} = 115 ± 45\) pc.

The MegaCam dataset can also be used to determine a lower limit on the absolute magnitude of the dwarf from the top three magnitudes of the RGB. Summing up the flux of all And XI stars yields \(M_{V,0}^{\text{AndXI}} = −4.6\) and \(M_{V,0}^{\text{AndXI}} = −5.8\) in the \(g\) and \(i\) bands respectively. Using the color equations between MegaCam \((g, i)\) magnitudes and \((V, i)\) INT magnitudes described in Ibata et al. (2006), and the INT color equations\(^5\) to derive \((V, J)\) Landolt magnitudes, yields \(M_{V,0}^{\text{AndXI}} = −5.0\) in the Landolt V band generally used for such measures. Although a significant part of the dwarf galaxy luminosity is not taken into account by considering only the top of the RGB, this value can be normalized by comparison with the MegaCam derived magnitude of And III with the value of \(M_{V,0}^{\text{AndIII}} = −10.2 ± 0.3\) measured by McConnachie et al. (2005) (in doing so, we assume that both And III and And XI have a similar luminosity function shape). MegaCam observations yield \(M_{V,0}^{\text{AndIII}} = −7.9\), a difference of 2.3 magnitudes compared to the McConnachie et al. (2005) value. The absolute magnitude of And XI should therefore approximately be \(M_{V,0}^{\text{AndXI}} ≈ M_{V,0}^{\text{AndXI}} = −2.3 = −7.3\). Obviously uncertainties on this value are significant but a comparison of the CMD of Figure 4 with that of And IX and X (Zucker et al. 2004, 2006\(^6\) and Urs Major (Willman et al. 2005) shows the RGB of And XI is less populated than that of these two other M31 satellites but more populated than that of UMa. Hence, And XI can naively be expected to be less luminous than And IX and X that have magnitudes of \(M_{V,0}^{\text{AndIX}} = −8.3 ± 0.5\) and \(M_{V,0}^{\text{AndIX}} = −8.1 ± 0.5\) but more luminous than UMAs that have \(M_{V,0}^{\text{UMA}} ≈ −6.5\). This is indeed what we find, yielding confidence in the measured value and suggesting an uncertainty of the order of ±0.5 mag.

\(^5\) http://www.ast.cam.ac.uk/~wfcsur/technical/photom/colours/
3.2 And XII

Among the three dwarf galaxies presented in this paper, And XII is the one with the least populated RGB with only ~20 stars. The CMD of stars within 3′ of its central position is shown in the left panel of Figure 4 and contains a well defined RGB between the isochrones of metallicities −2.3 and −1.3. The metallicity distribution once again contains a strong peak, with a median value of [Fe/H] = −1.5. In the following only stars within the −1.8 < [Fe/H] < −1.0 metallicity range are considered to belong to the dwarf. The distribution of these stars on the sky (bottom right panel of the same Figure) shows that, even though there are not many stars in this region of the sky, they do correspond to an overdensity, centered on (α, δ) = (0°47′22′′, +34°22′29′′). The probability that a group of stars are at the same time clustered on the sky and along a RGB is very low (see section 4), strengthening the hypothesis that And XII is a dwarf even though it is not directly visible on the MegaCam images.

The derived parameters are also consistent with those of a dwarf, though a very faint one. The half-light radius is determined as for And XI from the luminosity profiles that yield r1/2 = 0′55 ± 0.2, corresponding to r1/2 = 125 ± 45 pc assuming the same distance as M31. The absolute magnitude in the Landolt V band, determined as before from the MegaCam data, is MV, AndXII = −4.1 which is normalized to MV,0 = −6.4. A comparison with UMa ensures this value is sensible since both dwarfs contain a similar number of stars along their RGB and yield a similar absolute magnitude. However, given the low number of stars, this value has high uncertainties, of the order of ±1.0.

3.3 And XIII

The third faint dwarf galaxy that appears in the survey is presented in Figure 5. Once again, the CMD shows a RGB populated with ~30 stars within 3′ of the central position of the dwarf. The metallicity distribution is also well peaked, with a median value of [Fe/H] = −1.4. Since this peak has no clear limits, especially of the low metallicity side, we select And XIII stars within ±0.5 dex of the median value. The distribution of these stars on the sky (bottom right panel of Figure 5) reveals a roughly elliptical overdensity. Even if some contaminants are not taken out of the sample with this metallicity cut, the background correction that is performed using stars with the same metallicity in an annulus between 4′ and 10′ should correct for these. The mean position of this sample of stars is (α, δ) = (0°51′51′′, +33°00′16″) and is taken as the center of the dwarf.

The number of stars in And XIII is only a little higher than in And XII, and so the parameters of the dwarf are also difficult to derive precisely. As above, we use the distance of M31 for the dwarf to account for the difficulty of determining the tip of the sparsely populated RGB. The half-light radius is determined to be r1/2 = 0′5 ± 0.2, that is r1/2 = 115 ± 45 pc. The absolute magnitude in the V band, determined from the top three magnitudes of the RGB, is MV, AndXIII = −6.4 which is normalized as before to MV,0 = −6.9 ± 1.0.

Since the only visible feature of the observed images near And XIII is a cluster of galaxies, we check that the dwarf is not artificially created by misidentified background galaxies. It is reassuring that the distribution of galaxies within a few arcminutes of And XIII is very different from that of stars (see Figure 6). A two dimension K-S test (Press et al. 1992) yields a very low probability
(< 10^4) that both maps trace the same population and given that it is highly improbable that galaxies would align along a RGB, the presence of a background galaxy cluster close to the center of the dwarf has to be a coincidence and the dwarf is most certainly a genuine association of stars.

3.4 GC

The new globular cluster discovered in the MegaCam survey is located at (α, δ) = (0^h 50^m 42.5^s, +32° 54' 59.6") since the CASU pipeline is not well suited for separating overlapping stars in crowded regions, the region of the survey around the globular cluster was re-reduced using the Allstar package (Stetson 1994). The Allstar reduction is used for the region between 50 and 140 pixels (that is 9" to 26" of the center of the cluster) with objects with χ^2 < 2.0 considered to be stars. The CASU reduction is used over 140 pixels from the cluster to have a galaxy/star separation that is homogeneous with the rest of the survey (see the top panel of Figure 7).

The resulting CMD is presented in Figure 7 for a region of 1.5 around the cluster. Stars recovered with the Allstar reduction, which are closer to the center, are circled and help populate the RGB. In contrast with the new dwarf galaxies, the TRGB is easy to determine and the most luminous star of the branch (an Allstar object) appears to have a magnitude of I_0 = 20.43 ± 0.07. Converting this value to the Landolt I band where the TRGB is mainly invariant with metallicity (see e.g. Bellazzini, Ferraro & Pancino 2001) yields I_0 = 19.94 ± 0.13. Assuming a metallicity of [Fe/H] = −1.3 for the cluster (see below), the absolute magnitude of the tip is M_I = 4.05 ± 0.1 (Bellazzini, Ferraro & Pancino 2001), we derive a distance modulus of (m−M)_0 = 24.0 ± 0.2. This converts to a distance of 631 ± 58 kpc and at a projected distance of ~100 kpc from M31, that places the cluster at a distance of 175 ± 55 kpc from the Andromeda galaxy which makes it the most remote M31 globular cluster currently known, but places it well within the M31 virial radius.

In addition to the well populated RGB, the CMD also shows a horizontal branch from (g−i,i)_0 ∼ (−0.6,25.0) to (g−i,i)_0 ∼ (0.5,24.0). Even though these magnitudes are near the limits of the MegaCam data, the absence of similar features in the CMDs of Figures 3, 4 and 5 that correspond to larger regions indicates that it is related to the cluster. This horizontal branch, along with the TRGB can be used to determine the age and metallicity of the cluster from comparison with the Girardi et al. (2000) isochrones. The best two fits are shown in the two panels of Figure 7 and correspond to the oldest isochrones available, with an age of 17.8 Gyr, and with metallicities of −1.7 and −1.3 assuming no α enhancement. The fit with [Fe/H] = −1.3 produces the best results and even though an age of 17.8 Gyr is of course improbable, younger isochrones cannot reproduce the extent of the horizontal branch, meaning the cluster contains a very old population, as is expected for a globular cluster.

To derive the absolute magnitude of the cluster, we assume most of the luminosity comes from the integrated light in the inner regions. Hence, a wide aperture is used to derive the magnitude of the cluster as a single object, yielding background corrected magnitudes of m_g = 16.03 and m_i = 15.09. In this region of the sky, the extinction maps of Schlegel, Finkbeiner & Davis (1998) give E(B−V) = 0.08, thus we obtain m_{V,0} = 15.5 ± 0.2 where the uncertainties account for the color equations between MegaCam and Landolt magnitudes and the few stars in the outskirts of the cluster that are not taken into account by this method. Along with the distance modulus of (m−M)_0 = 24.0 ± 0.2 obtained previously, the absolute magnitude of GC is M_{V,0} = −8.5 ± 0.3. The half-light radius of the cluster is derived at the same time as r_1/2 = 0.76'' which converts to r_1/2 = 2.3 ± 0.2 pc at 631 ± 58 kpc. Hence, GC shows typical parameters for
a bright globular cluster (see e.g. Figure 7 of Huxor et al.
2004).

4 DISCUSSION

Although the globular cluster GC is clearly visible in the MegaCam images, it is not the case for the three dwarf galaxies so it is natural to wonder if the corresponding overdensities could be only random associations of stars. To test this possibility, we generate $10^5$ square degrees of artificial survey with the photometric characteristics of the 9 MegaCam fields in the outer regions of the M31 halo where no stream and/or structure is apparent. These fields have an average density of 3050 stars in the CMD region that correspond to M31 RGB stars. The number of neighbors within 1.5′ of each star in the artificial survey is determined and compared to the 24 and 34 stars within the same radius at the center of And XII and XIII. Figure 8 shows that the smaller of these two overdensities, And XII, is expected to be found randomly less than $10^{-3}$ times in a square-degree of the survey. So even in the whole 57 square-degrees of the artificial MegaCam survey, only $10^{-2}$ such structures are expected.

Moreover, this quick simulation does not take into account the clustering of stars along RGBs which means that randomly finding an And XII-like structure in the survey is even less probable. Since And XI and And XII contain more stars, we confidently conclude that the three stellar overdensities are dwarf galaxies and not random associations of stars.

Given their faintness, a detailed comparison of these dwarf galaxies with the other M31 satellites is premature and requires deeper observations. However, a few interesting points can already be discussed here. Firstly, the three dwarfs do not seem to extend the $[\text{Fe/H}] - M_V$ relation that is followed by the Andromeda satellites (Figure 8 left panel). The lack of other faint M31 satellites as well as the sparse RGB of the new dwarfs and the different techniques used to derive the metallicities of the various dwarfs make it hard to ascertain the extent of this offset or if it is due to a flattening of the relation. Nonetheless, at least for the Milky Way where the faint Boo and CVn dwarfs have recently been found (Belokurov et al. 2006; Zucker et al. 2006a), fainter dwarfs show more metal-poor populations. Alternatively, if as proposed by Ricotti & Gnedin (2003), these objects correspond to “true fossil” galaxies for which star formation was mainly suppressed after reionization, their simulations show that such objects are expected to have a wide metalliclicity spread of about 1.0 dex at the luminosity of And XI, XII and XIII (a few $10^4 L_\odot$). This could explain their high metallicity compared to other Andromeda satellites they tag as “true fossils” (e.g. And I, II, III, V or VI) but deeper observations are required in order to ascertain this classification by comparison with the other parameters they determine in their simulations (surface brightness, core radius, central luminosity density).

A significant difference between the new dwarfs and the other M31 satellites is their small size. Indeed, as can be seen on the right panel of Figure 9 they are two to three times smaller than the smallest previously-known Andromeda dwarfs. Although the values we derive here and recall in Table 1 have high uncertainties, these cannot account for this difference. A similar difference is observed between Andromeda and Milky Way satellites and has been proposed by McConnachie et al. (2005) to be due to differences in the formation and/or evolution of the dwarfs. In particular, Oh, Lin & Aarseth (1994) showed that a dwarf galaxy, of mass $M$ and on an orbit with semi-major axis $a$, and that lies in the logarithmic potential of its host has a tidal radius $r_t$ that is proportional to $r_t \propto a \left(\frac{M}{M_h}\right)^{1/3}$ where $M_h$ is the mass of the host halo within $a^3$. Even though a precise determination of the tidal radius of the dwarfs also depends on the eccentricity of the orbit of the dwarf but this dependency is weak.

Figure 8. Distribution of the number of neighbors within 1.5′ of each star in a square-degree of artificial MegaCam survey. $10^5$ square degrees were generated and averaged to obtain this distribution. The arrows represent the central density of And XII and XIII (24 and 34 neighbors within 1.5′) and have a very low probability to appear randomly in the survey.

Figure 9. Comparison of the parameters of the three new dwarfs (squares), with those of M31 satellites (triangles) and Milky Way satellites (circles). The correspondence between numbers and galaxies is presented on the left panel. The new dwarfs seem to be more metal-rich than the other Andromeda satellites, even though the lack of faint dwarfs prevent a firm conclusion (left). They are also two to three times smaller than the smallest previously-known M31 dwarfs and are about the size of most Milky Way satellites. (The data are taken from McConnachie et al. 2005 for most of Andromeda satellites, And X values are from Zucker et al. 2006a, UMa values from Willman et al. 2005, CVn values from Zucker et al. 2006b, Boo values from Belokurov et al. 2006 and from Mateo, 1998 otherwise.)
new dwarfs requires deeper observations, the measured $r_{1/2}$ can be used as an indicator of the size of the objects. Indeed, dwarf galaxies with a small half-light radius tend to have a small tidal radius (see e.g. Figure 5 of McC Connachie et al. 2003). If And XI, XII and XIII have been lying in the M31 halo along with the other Andromeda satellites, their projected distance from M31 ($\sim 8^\circ$) makes their semi-major axis at least $\sim 110$ kpc which is of the order of the semi-major axis of the other M31 dwarfs, implying that the observed difference in $r_{1/2}$ would be related to a difference in mass that should be about 10 to 30 times smaller than the other Andromeda dwarfs. While this could be due to their faintness, it has to be noted that measurements of the mass of the faint And IX (Chapman et al. 2003) and UMa (Kleyna et al. 2003) do not make them much less massive than brighter dwarfs ($\sim 10^7 M_\odot$). Alternatively, the small size of And XI, XII and XIII could be the telltale sign of different formation and/or evolution compared to the other M31 satellites. For instance, they could have been brought into the M31 halo as satellites of a recently merged or accreted galaxy. This scenario is all the more interesting since the new dwarfs all lie within only $2^\circ$ of one another which could be an indication that they form a linked sub-group. The presence of a newly found diffuse stellar stream with $[Fe/H] \sim -1.3$ not far from the three dwarfs in the M31 halo (see Ibata et al. 2003) also lends weight to this scenario, although the question of the survival of the dwarfs in such a merger remains open. The radial velocity of the dwarfs is obviously required to determine if they are linked but their faintness makes them very challenging even for spectrographs on the largest current telescopes.

If we assume that the galaxies are indeed linked, they should be at about the same distance. Under this assumption we sum up their CMDs and measure the RGB tip. This is done on Figure 10 where the MegaCam magnitudes have been converted to Landolt magnitudes using the Ibata et al. 2003 color equations.

Figure 10. Combined CMD of the And XI (filled circles), And XII (hollow circles) and And XIII (squares). The three dwarfs show strikingly similar RGBs, with a tip between $I = 20.3$ and $I = 20.85$. The luminosity function of the RGBs (the region between the two dashed line) is also shown on the right with the two arrows corresponding to the two determinations of the TRGB. The MegaCam magnitudes have been converted to Landolt magnitudes using the Ibata et al. 2003 color equations.

5 CONCLUSIONS

The inspection of the 57 square-degrees of our MegaCam survey of a quadrant of the M31 halo, from a projected distance of 50 kpc to 150 kpc, reveals the presence of four new satellites of the Andromeda galaxy down to $M_V = -6.4$. One of these is the farthest M31 globular cluster currently known. The other three satellites are faint dwarf galaxies that all lie within two degrees of one another, have a similar metallicity and are two to three times smaller than the smallest of previously-known M31 satellite galaxies. All these characteristics may indicate that they are linked together, have a common origin and were brought in the M31 halo by the same mechanism. Radial velocity measurements are necessary to confirm that they are kinematically associated and could also be used to determine if they exhibit the same high mass-to-light ratio that is found for the faint And IX dwarfs.
Three new faint dwarfs in the outer halo of the Andromeda galaxy (Chapman et al. 2005), UMa (Kleyna et al. 2005) and Boo (Muñoz et al. 2006). The sparsely populated RGBs of these new dwarfs will however prove a challenge for current telescopes. Deeper photometric observations are also required to better characterize the new structures, constrain their parameters and their stellar populations and search for tidal features in their outskirts. Their relation to the asymmetric distribution of M31 satellites (McConnachie & Irwin 2006) would also be very interesting to study.

The MegaCam survey also gives the first opportunity to study a significant portion of a galactic halo in search of substructures without any of the bias, such as projection effects and foreground contamination, that plague Milky Way studies. From the surveyed area, we estimate that a maximum of 45 \pm 20 satellites with $M_V \lesssim -6.4$ orbit around the Andromeda galaxy, which is one order of magnitude smaller than the number of substructures expected from CDM models, except if they reside in more massive halos than currently measured. The missing satellites thus do not seem to be highly dark matter dominated dwarf galaxies unless many are even fainter or more extended than those found here.

ACKNOWLEDGMENTS

We wish to thank the CFHT staff for performing the MegaCam observations in queue mode.
