Diversifying Metal–Ligand Cooperative Catalysis in Semi-Synthetic [Mn]-Hydrogenases

Hui-Jie Pan, Gangfeng Huang, Matthew D. Wodrich, Farzaneh Fadaei Tirani, Kenichi Ataka, Seigo Shima* and Xile Hu*

Abstract: The reconstitution of [Mn]-hydrogenases using a series of Mn⁴ complexes is described. These complexes are designed to have an internal base or pro-base that may participate in metal–ligand cooperative catalysis or have no internal base or pro-base. Only Mn⁴ complexes with an internal base or pro-base are active for H₂ activation; only [Mn]-hydrogenases incorporating such complexes are active for hydrogenase reactions. These results confirm the essential role of metal–ligand cooperation for H₂ activation by the Mn⁴ complexes alone and by [Mn]-hydrogenases. Owing to the nature and position of the internal base or pro-base, the mode of metal–ligand cooperation in two active [Mn]-hydrogenases is different from that of the native [Fe]-hydrogenase. One [Mn]-hydrogenase has the highest specific activity of semi-synthetic [Mn]- and [Fe]-hydrogenases. This work demonstrates reconstitution of active artificial hydrogenases using synthetic complexes differing greatly from the native active site.

Introduction

Artificial enzymes incorporating non-native metal cofactors while exhibiting native activities can serve as important tools for mechanistic studies of enzymes.¹ They also have potential applications in biocatalysis by increasing availability of hard-to-access enzymes as well as overcoming substrate specificity.²⁻⁴ Whereas many artificial enzymes have been designed to have an internal base or pro-base that may participate in metal–ligand cooperative catalysis or have no internal base or pro-base, only Mn⁴ complexes containing an internal base or pro-base are active for H₂ activation. And only such complexes could be used to reconstitute an active [Mn]-hydrogenase by incorporating a Mn⁴ mimic of the active site (1a) with the apo-enzyme of [Fe]-hydrogenase.⁵ The [Mn]-hydrogenase exhibited slightly higher specific activity per active metal site than that of a semi-synthetic [Fe]-hydrogenase incorporating an Fe¹¹ complex analogue (2a).⁶ The synthesis of a catalytically active [Mn]-hydrogenase paved the way for the current structure–activity study, where the active site is precisely modified via small molecule synthesis. An analogous study using Fe¹¹ mimics has been challenging due to their lower stability compared to the Mn⁴ ones.⁷

The mechanisms of H₂ activation in previously reported [Fe]- and [Mn]-hydrogenases all involve metal-ligand cooperation, where a basic 2-OH group generated by deprotonation of the 2-OH group of an pyridone derivative deprotonates the H₂ molecule coordinated to the metal ion (Figure 1B).⁸ In this study, we design and synthesize a series of Mn⁴ complexes with or without an internal base or pro-base (Figure 1C). Among the former complexes, the nature and position of the internal base or pro-base are different. Only Mn⁴ complexes containing an internal base or pro-base are active for H₂ activation. And only such complexes could be used to reconstitute an active [Mn]-hydrogenase. Based on the nature and position of the internal base or pro-base of their Mn⁴ cofactors, certain [Mn]-hydrogenases operate by a non-native metal-ligand cooperation mode. One such [Mn]-hydrogenase exhibits the highest activity among semi-synthetic [Mn]- and [Fe]-hydrogenases. The work demonstrates the construction of functional hydrogenases using synthetic complexes that operate via a new-to-nature reaction mechanism. This strategy might be used to expand the functions of Hmd hydrogenases beyond native reactions using novel substrates other than methenyl-/methylenyl-H₂MPT and H₂.
which contains an enolate ligand (Figure 2A). By addition of 1.1 equivalents of 18-crown-6 to 3, 3(18-crown-6) was formed and isolated.

We estimated pKₐ of relevant OH, CH, and amide acids in DMSO using NMR titration experiments (Supporting Information, section 1.4). The pKₐ of the 2-OH group in 1a and 1b were 9.0 ± 0.1 and 8.8 ± 0.1, respectively, that of the (C(6)-H) moiety in 1c was 13.7 ± 0.1, and that of the conjugated acid of 1d was between 1.6–3.6.

The IR spectra of 1a, 1b and 1c exhibit four ν(CO) peaks (Supporting Information, Table S1), consistent with the complexes having four CO ligands. In the IR spectra of 1d and 1e, however, only 3 ν(CO) peaks are observed due to peak overlapping. In the ¹³C NMR spectra of 1a–1e, the four CO ligands give only three peaks (Supporting Information, Table S2), indicating that the two trans-orienting CO ligands are equivalent on the NMR scale. Overall, the CO ligands in 1a–1e have similar ν(CO) frequencies and ¹³C NMR shifts, indicating a similar electronic property among these complexes. The substituents at the 2-position of the pyridine ligand have only a minor influence on the electron density at the Mn center. Upon deprotonation of the methylene group in 1e to form an enolate group in 3(18-crown-6), the ¹H NMR chemical shift of the remaining proton on the methylene carbon changed from 3.91 ppm to 5.19 ppm, consistent with the formation of an alkene moiety. This interpretation is also supported by IR spectra, which indicates a more electron-rich Mn center in 3(18-crown-6) than in 1e (Supporting Information, Table S1).

X-ray crystallography confirms 1b–e and 3(18-crown-6) as Mn₄ tetra(carbonyl) complexes ligated by a bidentate N-C ligand derived from pyridine (Figure 2B).[8] The coordination geometry of Mn ions is best described as pseudo-octahedral. The N-C ligand forms a non-planar five-membered metallo-cycle with the Mn ion. Among the four CO ligands, the one trans to the pyridyl N ligand forms the shortest M-CO bond (Mn-C₆; Supporting Information, Table S3), consistent with N(pyridine) being the weakest trans ligand among N-, (pyridine), C(acyl), and C(CO). The M–CO distances for the other three CO ligands are rather similar (Supporting Information, Table S3). Mn ion and the ortho-O atom are confirmed metal–ligand cooperation sites. Their distances in 1a and 1b are about 3.2 Å. Notably, the distances of the Mn ion to the C₆ or N₂ atom in 1c and 1d, respectively, are only about 3.0 Å. This short distance substantiates the possibility of the C₆ and N₂ atoms serving as an alternate metal-ligand cooperative site. Upon deprotonation of 1e to form 3(18-crown-6), the C₅–C₆ bond shortened from 1.533(9) Å to 1.396(2) Å, and the C₅–O₅ bond elongated from 1.216(7) Å to 1.250(2) Å. These changes confirm the presence of a coordinating enolate moiety in 3(18-crown-6).

Only irreversible oxidation and reduction were observed in the cyclic voltammograms of 1a–e (Supporting Information, Figure S40). Judging from the peak potentials for the oxidation, the electron density of the Mn⁴ ion follows the following order: 1a ≈ 1b ≈ 1c ≈ 1e > 1d.

An H₂/D₂ exchange assay was employed to probe the activities of 1b–1e and 3(18-crown-6) in H₂ activation (Table 1; for more information, see the Supporting Informa-
The reactions were conducted under a mixed atmosphere of D₂ (8 bar) and H₂ (12 bar). The formation of HD indicated H₂ activation. The initial Mn complexes remained the only identifiable Mn species during and after the reaction; no Mn-H intermediates were observed. All complexes except 1e catalyzed H₂/D₂ exchange in the presence of an external base (Table 1). The activities have the following order: 1a > 1b ≈ 1c > 1d when N-methylpyrrolidine (MP) was used as the external base (entries 1–3, Table 1). The lower activity of 1b compared to 1a suggests that the two methyl groups at the C6 position of the ligand hinders H₂ activation (entries 1 and 2, Table 1). The reactivity of 1c depended on the base: the reaction was negligible in the absence of base, but with 2 equiv of KOtBu, the HD: D₂ ratio increased to 1:2.2 (entry 7).

**Tabelle 1: Summary of the results of H₂/D₂ exchange experiments.**

| Entry | Complex | Base       | t  | HD: D₂ ratio | Relative reactivity |
|-------|---------|------------|----|--------------|-------------------|
| 1     | 1a      | MP         | 6h | 1:3.3        | medium            |
| 2     | 1b      | MP         | 6h | 1:16.8       | medium low        |
| 3     | 1c      | MP         | 6h | 1:16.8       | medium low        |
| 4     | 1d      | MP         | 6h | 1:43.8       | low               |
| 5     | 1e      | MP         | 6h | < 1:100      | negligible        |
| 6     | 1c      | 1.0 equiv KOtBu | 6h | < 1:100      | negligible        |
| 7     | 1c      | 2.0 equiv KOtBu | 10 min | 1:2.2 | high             |
| 8     | 1c      | Et₂N       | 6h | < 1:100      | negligible        |
| 9     | 1e      | 1.0 equiv KOtBu | 6h | < 1:100      | negligible        |
| 10    | 1e      | 2.0 equiv KOtBu | 6h | < 1:100      | negligible        |
| 11    | 3(18-crown-6) | – | 6h | < 1:100      | negligible        |
| 12    | 3(18-crown-6) | 1.0 equiv KOtBu | 30 min | < 1:100 | negligible        |
| 13    | 3(18-crown-6) | 1.0 equiv KOtBu | 30 min | 1:3.2 | high             |
| 14    | 1a      | 2.0 equiv KOtBu | 6h | 1:18.7       | medium low        |

[a] Conditions: D₂ (8 bar), H₂ (12 bar), Mn complex 0.03 mmol, CD₃CN 0.4 mL at ambient temperature; MP = N-methyl pyrrolidine, 5.0 equivalent of base relative to the Mn complex. [b] Based on time-averaged HD: D₂ ratio determined by ¹H NMR.
strongly on the basicity as well as the quantity of the external base. In the presence of one equivalent of a strong base KO\textsubscript{2}Bu (entry 6, Table 1), no \textit{H}_{2}D\textsubscript{2} exchange was observed. Increasing the equivalent of KO\textsubscript{2}Bu to 2 equivalents led to a rapid \textit{H}_{2}D\textsubscript{2} exchange (entry 7, Table 1). This result could be rationalized by considering that the first equivalent of KO\textsubscript{2}Bu deprotonated the methylene group in \textit{1c} to form an enolate complex similar to \textit{3}, which could catalyze \textit{H}_{2}D\textsubscript{2} exchange only in the presence of an external base (the second equivalent of KO\textsubscript{2}Bu). To probe this hypothesis, 3(18-crown-6) was used as catalyst. Without an external base, no \textit{H}_{2}D\textsubscript{2} exchange took place (entry 11, Table 1). With 1.0 equiv of KO\textsubscript{2}Bu, there was still no rapid \textit{H}_{2}D\textsubscript{2} exchange (entry 12, Table 1). This result was rationalized by the lack of proton in the system, which is necessary to mediate H/D exchange after \textit{H}_{2}D\textsubscript{2} activation. Indeed, when 1.0 equiv of HO\textsubscript{2}Bu was added to the reaction system, fast \textit{H}_{2}D\textsubscript{2} exchange was observed (entry 13, Table 1). For \textit{1c}, the rate of \textit{H}_{2}D\textsubscript{2} exchange was much higher in the presence of KO\textsubscript{2}Bu over MP. This rate difference was attributed to an incomplete formation of the enolate complex in the presence of MP. Indeed, the \textit{pK}_{a} of the methylene proton in \textit{1c} was about 13.7 in DMSO, higher than that of MPH\textsuperscript{+} (10.6). For \textit{1a}, a similar rate of \textit{H}_{2}D\textsubscript{2} exchange was observed in the presence of KO\textsubscript{2}Bu or MP (entries 1 and 14, Table 1). This result could be rationalized considering that the 2-OH proton in \textit{1a} has a \textit{pK}_{a} of 9.0 in DMSO so that both MP and KO\textsubscript{2}Bu are strong enough to fully deprotonate.

We reconstituted semi-synthetic [Mn]-hydrogenases incorporating complexes \textit{1a}–\textit{1e} as the metal co-factors following a previously established protocol.\cite{1a} Due to the potential instability of Mn complexes, the reconstitution experiments were performed as soon as possible after the chemical synthesis (see the Supporting Information). Two equivalents of a Mn complex was dissolved in a methanol solution containing 1% acetic acid. This solution was then mixed with a solution of one equivalent of the [Fe]-hydrogenase apoenzyme from \textit{Methanocaldococcus jannaschii} heterologously produced in \textit{Escherichia coli} in the presence of 2 mM guanosine monophosphate (GMP). We reported earlier that external GMP slightly increased the specific activity of semi-synthetic [Fe]-hydrogenase and [Mn]-hydrogenase.\cite{1a,1c} The resulting [Mn]-hydrogenases were named as jHmd (wild)-\textit{1a}, jHmd (wild)-\textit{1b}, jHmd (wild)-\textit{1c}, jHmd (wild)-\textit{1d}, and jHmd (wild)-\textit{1e}, respectively. Mutant enzymes were prepared in the same way but with the His\textsubscript{14}A and Cys176A apoenzymes. They are named as jHmd (H14A)-\textit{1a}, jHmd (H14A)-\textit{1b}, jHmd (H14A)-\textit{1c}, jHmd (H14A)-\textit{1d}, and jHmd (H14A)-\textit{1e}.

The activities of [Mn]-hydrogenases were measured photometrically for both the forward (reduction of methenyl-H\textsubscript{MPT}\textsuperscript{+} with \textit{H}_{2}) and the reverse (\textit{H}_{2} production from methylene-H\textsubscript{MPT} reactions (Table 2). The reconstituted jHmd (wild) enzymes other than jHmd (wild)-\textit{1e} exhibited the Hmd activity. In native [Fe]-hydrogenase, the FeGP cofactor is covalently bound to the protein via the Cys176-S-metal coordination. In our previous report as well as this work, a dramatic loss of activity was detected for jHmd (C176A)-\textit{1a} (0.06 ± 0.07 U mg\textsuperscript{−1}) compared to jHmd (wild)-\textit{1a} (7.8 ± 0.7 U mg\textsuperscript{−1}). The small residual activity suggests that other interactions such as hydrogen bonding between a metal complex and protein might lead to incorporation of a metal complex in the active site, albeit less efficiently. Additional Cys176Aa mutation studies, however, suggest Cys176-metal coordination is required for most Mn complexes. Thus, jHmd (C176A)-\textit{1b}, jHmd (C176A)-\textit{1c}, jHmd (C176A)-\textit{1d} and jHmd (C176A)-\textit{1e} were totally inactive in both forward and reverse reactions (Table 2, entries 12–15). Based on these properties, we assumed that through reconstitution, the Mn complexes were specifically incorporated into the active site, in which Mn complex coordinated with Cys176-S. We cannot exclude the possibility that Mn complexes bind at the active site without Cys176S-Mn bonding though. Infrared spectrum of the reconstituted enzymes were similar to those of the free Mn complexes without protein, which indicated that sub-

### Table 2: Occupancy rates and actual specific activities of [Mn]-hydrogenases.\cite{1b}

| Entry | Samples          | Occupancy [%] | Actual specific activity (U mg\textsuperscript{−1})<sup>(forward)</sup> | Actual specific activity (U mg\textsuperscript{−1})<sup>(reverse)</sup> |

[a] ND: not detected (the specific activity was less than 0.02 U mg\textsuperscript{−1}). [b] The actual specific activities were obtained via dividing the measured specific activities by the active site occupancies. [c] Measured specific activity.
stantial Mn complex was non-specifically adsorbed on other parts of the protein (Supporting Information, Figure S41). Previously we fortuitously obtained a sample where the majority of adsorbed Mn complex was incorporated into the active site. The frequency of the two CO bands are similar to those of the native [Fe]-hydrogenase, which supported the binding mode of the Mn complex to the protein by Cys176-S-metal bonding. Based on the intensities of v(CO) band and the amide II band of the protein, we were able to estimate the occupancy of the active site of samples of jHmd (wild)-1a.[14] Previous study shown that non-specifically adsorbed Mn complexes had no contribution to the detected enzymatic activities.[14]

In this study, for [Mn]-hydrogenases incorporating other Mn complexes, we were not able to obtain samples with only specifically adsorbed complexes. Thus, we developed an alternative and more general method for estimating the occupancy of the active site (Supporting Information, Section 2.2). We assume that jHmd (C176A) cannot bind a Mn complex in the active site as the sulfur ligand from the Cys176 is removed. The v(CO) peaks in reconstituted jHmd (C176A) samples could be attributed to non-specifically bound Mn complexes. Meanwhile, the v(CO) peaks in reconstituted jHmd (wild) samples were due to both specifically and non-specifically adsorbed Mn complexes. By subtracting the amount of non-specifically bound complexes, we obtained the occupancies of the reconstituted jHmd (wild) samples (Scheme S2 for methods and Table 2 and the Supporting Information, Table S5 for results). We acknowledge a substantial level of uncertainty in this analysis due to, for example, a limited spectral resolution or the possibility that jHmd (C176A) and jHmd (wild) would unspecifically bind a different amount of a given Mn complex. Nevertheless, this analysis shall give correct qualitative trends. The occupancy of jHmd (wild) 1a obtained by this method (20.3%) is nearly the same as that estimated by the previous method (20%).[14] The occupancies of jHmd (wild) 1a, 1c and 1d were similar (from about 15 % to 25 %). Notably, reconstitution using complexes 1b and 1e bearing two methyl groups α-to the acyl donor had much higher occupancies (70.9 % and 58.8 %, respectively).

The measured specific activities were divided by the active site occupancies to give the actual specific activities, which could be compared among different enzymes. [Mn]-hydrogenases reconstituted with 1b–1d, along with 1a, were all catalytically active for at least the forward reaction. The [Mn]-hydrogenase reconstituted with 1e was inactive for both forward and reverse reactions.

The activity of jHmd (wild)-1a determined on samples prepared in this study (7.8 ± 0.7 for the forward reaction) was nearly identical to that of previously reported sample.[14] The activity of jHmd (wild)-1b (1.1 ± 0.17 U mg⁻¹ for the forward reaction) was about 14 % of that of jHmd (wild)-1a, suggesting that the steric hindrance due to the two additional methyl groups at the C6 position of the ligand slows down the reaction. jHmd (wild)-1d, which contains a tertiary amide basic site, had similar activity (9.3 ± 1.6 U mg⁻¹ for the forward reaction) as jHmd (wild)-1a. The most active enzyme was jHmd (wild)-1c whose precursor complex has an enolate basic site upon deprotonation. Its actual specific activities for the forward reaction and reverse reaction were 37 ± 17 U mg⁻¹ and 37 ± 16 U mg⁻¹, which are about 4 and 37 times higher than those of jHmd (wild)-1a, respectively. The activities of jHmd (wild)-1e were about 5 times and 8 times higher than those of semi-synthetic [Fe]-hydrogenase reconstituted with Fe complex 2a.[15] These activities were about 10% of those of native [Fe]-hydrogenase which has the FeGP cofactor. Note that semi-synthetic [Fe]-hydrogenase reconstituted with an analogous Fe complex 2b (Figure 1A) was inactive. We attributed the difference in activity to the instability of 2b upon deprotonation of the methylene(acyl) group as well as the generally lower activity of Fe mimics compared to Mn mimics.[7a,9]

In the native [Fe]-hydrogenase, His14 is proposed as a proton acceptor from 2-OH of pyridinol of the FeGP cofactor.[8] To probe the function of His14 as a base and a part of the proton relay (Supporting Information, Figure S45), we conducted reconstitution studies using His14Ala mutant of the apoenzyme. The resulting [Mn]-hydrogenases, jHmd (H14A)-1n (n = a–d) had essentially no detectable activity for both forward and reverse reactions except for jHmd (H14A)-1d (Table 2). This result suggests that His14 is a necessary base to deprotonate not only 2-OH but also methylene(acyl) groups to form an internal O*- or enolate basic sites in the Mn complexes. In contrast, jHmd (H14A)-1d retained substantial activity of jHmd (wild)-1d. This result could be understood by considering that the Mn complex 1d has already a basic amide site, and once protonated, the proton on it is rather acidic and can be transferred by H₂O molecule.

**Discussion**

The results in Table 1 indicate that an internal base in a Mn complex is necessary for H₂ activation. The H₂/D₂ exchange was observed only in the presence of an external base because this exchange requires a H*/D* exchange in addition to H₂ activation.

It was previously shown, based on DFT computations, that the mechanism of H₂ activation on 1a involved first deprotonation of the 2-OH group, followed by dissociation of a CO ligand trans to the acyl ligand, H₂ coordination, and then intramolecular heterolytic H₂ cleavage (Figure 3A).[14] A same mechanism is expected for H₂ activation on 1b, but not on 1c and 1d where the internal bases (C6 or N2) are located at the 6-position of the pyridine moiety. For the latter two catalysts, we propose an analogous mechanism. In the case of 1e (Figure 3B), deprotonation of the catalyst gives a coordinated enolate anion. Replacement of a CO cis to the acyl ligand by H₂ then yields a Mn-H₂ complex where the H₂ can be heterolytically cleaved by the cooperative action of the O anion of the enolate and the Mn center. In support of this mechanism, we found significant D incorporation at the methylene position during both H₂/D₂ exchange assay and H*/D* exchange assay experiments (Supporting Information, Figure S14). A similar mechanism for H₂ activation was previously proposed for Mn[10] as well as Fe and Ru complexes.[11] Note that deprotonation of methylene(acyl)
group by a base was also reported for Fe models of [Fe]-hydrogenase, but the resulting enolate anion did not have a catalytic role.\textsuperscript{[9]} In the case of 1d (Supporting Information, Figure S13), no deprotonation is needed to create a basic site. Thus, the reaction occurs by replacement of a CO by H\textsubscript{2} followed by heterolytic H\textsubscript{2} cleavage via a Mn-O cooperation.

The results in Table 2 indicate a suitable internal base in the Mn complex is required for reconstituting an active [Mn]-hydrogenase. The results are consistent with the intrinsic activities of Mn complexes (Table 1). Unlike Mn complexes which require an external base to generate the internal base or to mediate H\textsuperscript{+}/D\textsuperscript{+} exchange, [Mn]-hydrogenases require no external base for function, indicating that a basic protein residue exists near the active site. This residue is likely the His14 group which is important for the activity.\textsuperscript{[60]} The rate of H\textsubscript{2} activation by a [Mn]-hydrogenase is much higher than that of the corresponding Mn complex alone (see the Supporting Information, Table S6 for estimated TOFs). The smallest difference was found for jHmd (wild)-1c and 1c (with 2.0 equiv KO\textsubscript{Bu}, entry 7 Table 1) but the difference is still large; the former has a TOF of about 24 s\textsuperscript{-1}, while the latter has a TOF about 0.03 s\textsuperscript{-1}. The differences presumably highlight the essential role of protein environment for efficient catalysis.

The reactivity trend of [Mn]-hydrogenases does not correlate with that of the Mn complexes alone. Different multi-step reactions and different conditions are involved in enzyme and H\textsubscript{2}/D\textsubscript{2} exchange assays. The observed reaction rates do not reflect the reactivity towards the same reaction step, i.e., hydrogen activation, because energetics and kinetics of other steps such as deprotonation or hydride transfer also contribute to the overall rate. Interestingly, the most active [Mn]-hydrogenase contains a Mn complex (1c) that is most active for H\textsubscript{2}/D\textsubscript{2} exchange under a strong base. Once activated (deprotonated), this complex has the strongest internal base. We hypothesize that a strong internal basic site is beneficial for metal-ligand cooperative H\textsubscript{2} activation as long as this basic site is easily accessible in the catalytic cycle. The reactivity trend of [Mn]-hydrogenases, however, does not linearly correlate with the basicity of internal bases. For example, jHmd (wild)-1a and jHmd (wild)-1d have similar activity, but the internal bases at their active sites have quite different basicities. We hypothesize that for these cases the overall Mn cofactor is expected to have more possibilities in orientations in the active site. We envision at least two models. In model A (Figure 4), the acyl ligand of a Mn complex is distal to His14, which is the orientation found for FeGP in the native [Fe]-hydrogenase. The 2-OH group is close to His14 so that proton relay from 2-OH to His14 to form a basic O\textsuperscript{-} group is facile. H\textsubscript{2} is activated through a mechanism described in Figure 3 A. This model can explain the reactivity of jHmd (wild)-1a and jHmd (wild)-1b. In model B (Figure 4), the acyl/carbamoyl ligand of a Mn complex is proximal to His14. Proton relay from X (X = C or N) to His14 as well as from O to X is again facile. H\textsubscript{2} is activated through a mechanism described in Figure 3 B. This model can explain the reactivity of jHmd (wild)-1c and jHmd (wild)-1d. The p\textsubscript{K} of the 2-OH group in 1a and 1b, as well as that of the methylene group in 1c, is expected to be much lower in water than in DMSO. As a reference, acetic acid has a p\textsubscript{K} of 12.3 in DMSO but only 4.8 in water. Thus, proton relay of these groups with His14 in water appears feasible.

The [Fe]-hydrogenases containing the FeGP cofactor or an iron mimic, as well as jHmd (wild)-1c, catalyze the forward and reverse reactions in a similar rate.\textsuperscript{[62]} However, for jHmd (wild)-1a, jHmd (wild)-1b, and jHmd (wild)-1d, the reverse reaction was either much slower than the forward reaction or could not be detected. The reactions were conducted under
the same conditions for both [Mn] and [Fe]-hydrogenases: the pH for the forward reaction was 7.5 while that for the reverse reaction was pH 6.0. We suspect that the much faster forward reactions for jHmd (wild)-1a, jHmd (wild)-1b, and jHmd (wild)-1d under the employed assay conditions originates from the non-optimal conditions to generate the internal proton relay for the reverse reactions on jHmd (wild)-1a, jHmd (wild)-1b, and jHmd (wild)-1d. The internal bases in 1a, 1b, and 1d are weaker than that in 1c. It is possible that at pH 6.0, the former basic sites are nearly always in the basic forms, i.e., 2-O- for 1a and 1b and C(O)N(Me) for 1d, which limits the turnover rate for the reverse reaction.

**Conclusion**

We have developed a series of Mn' mimics of the active site of [Fe]-hydrogenase. These complexes are designed to have either a 2-OH group, an enolizable CH2 group, or a tertiary amide group that can serve as an internal base, or no internal base. Only the complexes with internal bases are able to heterolytically cleave H2. Incorporation of the Mn complexes into the apo-enzyme of [Fe]-hydrogenases result in semi-synthetic [Mn]-hydrogenases. The Mn complexes are predicted to bind to the protein via the Cys176 residue. Only the [Mn]-hydrogenases containing Mn complexes with internal bases are catalytically active for the native reactions of [Fe]-hydrogenase. H2 activation by both Mn complexes alone and [Mn]-hydrogenases involves metal-ligand cooperation, where a basic ligand moiety serves as an internal base to deprotonate coordinated H2. In addition to the cooperation mode found in [Fe]-hydrogenase which involves the 2-O- group of the pyridine ligand of the active site, new cooperation modes involving either an enolate or an amide at the 6-position of the pyridine ligand as the internal base are operative. Moreover, the [Mn]-hydrogenase where an enolate moiety serves as the internal base is about 5 times and 8 times more active (forward reaction) than its Mn and Fe counterparts where a 2-O- group serves as the internal base, respectively. This result represents a good example where a new-to-nature reaction mechanism[12] results in substantial activity for the native reaction of an enzyme. The work indicates the possibility to incorporate synthetic complexes distinct from the native active site to reconstitute active Hmd hydrogenases, which can potentially open up new areas of applications such as activation of other small molecules and organic synthesis.
