Conjunctions of Among Constraints

Víctor Dalmau

Dept. of Information and Communication Technologies, Universitat Pompeu Fabra

Abstract. Many existing global constraints can be encoded as a conjunction of among constraints. An among constraint holds if the number of the variables in its scope whose value belongs to a prespecified set, which we call its range, is within some given bounds. It is known that domain filtering algorithms can benefit from reasoning about the interaction of among constraints so that values can be filtered out taking into consideration several among constraints simultaneously. The present paper embarks into a systematic investigation on the circumstances under which it is possible to obtain efficient and complete domain filtering algorithms for conjunctions of among constraints. We start by observing that restrictions on both the scope and the range of the among constraints are necessary to obtain meaningful results. Then, we derive a domain flow-based filtering algorithm and present several applications. In particular, it is shown that the algorithm unifies and generalizes several previous existing results.

1 Introduction

Global constraints play a major role in constraint programming. Very informally, a global constraint is a constraint, or perhaps more precisely, a family of constraints, which is versatile enough to be able to express restrictions that are encountered often in practice. For example, one of the most widely used global constraints is the 'All different' constraint, \texttt{AllDiff}(S) where \( S = \{x_1, \ldots, x_n\} \) is a set of variables, which specifies that the values assigned to the variables in \( S \) must be all pairwise different. This sort of restriction arises naturally in many areas, such as for example scheduling problems, where the variables \( x_1, \ldots, x_n \) could represent \( n \) activities that must be assigned different times of a common resource.

Besides its usefulness in simplifying the modeling or programming task, global constraints also improve greatly the efficiency of propagation-search based solvers. This type of solver performs a tree search that constructs partial assignments and enforces some sort of propagation or local consistency that prunes the space search. Different forms of consistency, including (singleton) bounds consistency, (singleton, generalized) arc-consistency, path consistency and many others, can be used in the propagation phase. One of the most commonly used forms of local consistency is \textit{domain consistency}, also called generalized arc-consistency. A domain consistency algorithm keeps, for every variable \( v \), a list, \( L(v) \), of feasible values, which is updated, by removing a value \( d \) from it, when some constraint
in the problem guarantees that \( v \) cannot take value \( d \) in any solution. One of the key reasons of the success of global constraints is that they enable the use of efficient filtering algorithms specifically tailored for them.

Several constraints studied in the literature including `ALLDIFF`\(^{[24]}\), `GCC`\(^{[27]}\), `SYMMETRIC-GCC`\(^{[21]}\), `SEQUENCE`\(^{[6]}\), `GLOBALSEQUENCING`\(^{[34]}\), `ORDERED-DISTRIBUTE`\(^{[28]}\), and `CARDINALITYMATRIX`\(^{[33]}\) can be decomposed as the conjunction of a simpler family of constraints, called among constraints\(^{[6]}\). An among constraint has the form \( \text{AMONG}(S, R, \text{min}, \text{max}) \) where \( S \) is again a set of variables called the `scope`, \( R \) is a subset of the possible values, called the `range`, and \( \text{min}, \text{max} \) are integers. This constraint specifies that the number of variables in \( S \) that take a value in \( R \) must be in the range \( \{ \text{min, \ldots, max} \} \). For example, the constraint `ALLDIFF(S)` can be expressed as the conjunction of constraints \( \text{AMONG}(S, \{d_1\}, 0, 1), \ldots, \text{AMONG}(S, \{d_k\}, 0, 1) \) where \( d_1, \ldots, d_k \) are the set of all feasible values for the variables in \( S \).

Besides encoding more complex global cardinality constraints, conjunctions of among constraints, (CAC), appear in many problems, such as Sudoku or Latin squares. In consequence, CACs have been previously studied\(^{[10,32,38]}\), specially the particular case of conjunctions of `ALLDIFF` constraints\(^{[2,3,9,13,22,23,25]}\). Although deciding the satisfiability of an arbitrary conjunction of among constraints is NP-complete\(^{[32]}\) this body of work shows that sometimes there are benefits in reasoning about the interaction between the among constraints. Hence, it is important to understand under which circumstances among constraints can be combined in order to endow CSP solvers with the ability to propagate taking into consideration several among constraints simultaneously. The aim of the present paper is to contribute to this line of research. To this end we first observe that restrictions on both the scope and the range of the among constraints are necessary to obtain meaningful results. Then we embark in a systematic study of which such restrictions guarantee efficient propagation algorithms. In particular, we introduce a general condition such that every CAC satisfying it admits an efficient and complete domain filtering algorithm. This condition basically expresses that the matrix of a system of linear equations encoding the CAC instance belongs to a particular class of totally unimodular matrices known as network matrices. This allows to reformulate the domain filtering problem in terms of flows in a network graph and apply the methodology derived by Régis\(^{[30,31]}\). The algorithm thus obtained, although simple, unifies and generalizes existing domain filtering algorithms for several global constraints, including `ALLDIFF`, `GCC`, `SEQUENCE`, `SYMMETRIC-GCC`, `ORDERED-DISTRIBUTE` as well as for other problems expressed as conjunctions of among constraints in\(^{[29,32]}\). A nice feature of our approach is that it abstracts out the construction of the network flow problem, so that when exploring a new CAC one might leave out the usually messy details of the design of the network graph and reason purely in combinatorial terms.

Several filtering methods have been obtained by decomposing a global constraint into a combination of among constraints. For example the first polynomial-time filtering algorithm for the `SEQUENCE` constraint\(^{[53]}\) is obtained explicitly
in this way. However, there have been very few attempts to determine systematically which particular conjunctions of among constraints allow efficient filtering algorithms. The seminal paper in this direction is [31] which identifies several combinations of among and GCC constraints that admit a complete and efficient domain filtering algorithm (see Section 6 for more details). Our approach is more general as it subsumes the tractable cases introduced in [31]. Another closely related work is [29] where two tractable combinations of boolean CACs, called TFO and 3FO, are identified. The approach in [29] differs from ours in two aspects: it deals with optimization problem and also considers restrictions on the min and max parameters of the among constraints while we only consider restriction on the scope and range. A different family of CACs has been investigated in [10] although the work in [10] focuses in bound consistency instead of domain consistency.

Other approaches to the design of filtering algorithms for combinations (but not necessarily conjunctions) of global (but not necessarily among) constraints are described in [4,7,8]. The method introduced in [4] deals with logical combinations of some primitive constraints but differs substantially from ours in the sense that it cannot capture a single among constraint. The work reported in [7,8] does not guarantee tractability.

Several proofs are omitted due to space restrictions. They can be found in the Appendix.

2 Preliminaries

A conjunction of among constraints, (CAC) is a tuple $\langle V, D, L, C \rangle$ where $V$ is a finite set whose elements are called variables, $D$ is a finite set called domain, $L : V \rightarrow 2^D$ is a mapping that sends every variable $v$ to a subset of $D$, which we call its list, and $C$ is a finite set of constraints where a constraint is an expression of the form $\text{Among}(S, R, \text{min}, \text{max})$ where $S \subseteq V$ is called the scope of the constraint, $R \subseteq D$ is called range of the constraint, and $\text{min}, \text{max}$ are integers satisfying $0 \leq \text{min} \leq \text{max} \leq |S|$.

A solution of $\langle V, D, L, C \rangle$ is a mapping $s : V \rightarrow D$ such that $s(v) \in L(v)$ for every variable $v \in V$ and $\text{min} \leq |\{v \in S \mid s(v) \in R\}| \leq \text{max}$ for every constraint $\text{Among}(S, R, \text{min}, \text{max})$ in $C$.

Example 1. (GCC and ALLDIFF constraints) The global cardinality constraint[1], GCC [27] corresponds to instances $\langle V, D, L, C \rangle$ where all the constraints have the form $\text{Among}(V, \{d\}, \text{min}, \text{max})$ with $d \in D$. The ALLDIFF constraint is the particular case obtained when, additionally, $\text{min} = 0$ and $\text{max} = 1$.

Let $I = \langle V, D, L, C \rangle$ be a CAC. We say that a value $d \in D$ is supported for a variable $v \in V$ if there is a solution $s$ of $I$ with $s(v) = d$. In this paper we focus in the following computational problem, which we will call domain filtering: given a CAC, compute the set of all the non supported values for each of its variables.

\footnote{We want to stress here that a global constraint is not a single constraint but, in fact, a family of them.}
This definition is motivated by the following scenario: think of \((V, D, L, C)\) as defining a constraint which is part of a CSP instance that is being solved by a search-propagation algorithm that enforces domain consistency. Assume that at any stage of the execution of the algorithm, \(L\) encodes the actual feasible values for each variable in \(V\). Then, the domain filtering problem is basically the task of identifying all the values that need to be pruned by considering the constraint encoded by \((V, D, L, C)\).

3 Network hypergraphs

An hypergraph \(H\) is a tuple, \((V(H), E(H))\), where \(V(H)\) is a finite set whose elements are called nodes and \(E(H)\) is set whose elements are subsets of \(V(H)\), called hyperedges. An hypergraph is totally unimodular if its incidence matrix \(M\) is totally unimodular, that is, if every square submatrix of \(M\) has determinant \(0, +1\), or \(-1\). In this paper we are concerned with a subset of totally unimodular hypergraphs called network hypergraphs. In order to define network hypergraph we need to introduce a few definitions.

An oriented tree \(T\) is any directed tree obtained by orienting the edges of an undirected tree. A path \(p\) in \(T\) is any sequence \(x_1, e_1, x_2, \ldots, e_{n-1}, x_n\) where \(x_1, \ldots, x_n\) are different vertices of \(T\), \(e_1, \ldots, e_{n-1}\) are edges in \(T\) and for every \(1 \leq i < n\), either \(e_i = (x_i, x_{i+1})\) or \(e_i = (x_{i+1}, x_i)\). The polarity of an edge \(e\) \(\in E(T)\) wrt. \(p\) is defined to be +1 (or positive) if \(e = (x_i, x_{i+1})\) for some \(1 \leq i < n\), -1 (or negative) if \(e = (x_{i+1}, x_i)\) for some \(1 \leq i < n\), and 0 if \(e\) does not appear in \(p\). A path \(p\) has positive (resp. negative) polarity if all its edges have positive (resp. negative) polarity. Paths with positive polarity are also called directed paths. Since an oriented tree does not contain symmetric edges, we might represent a path by giving only its sequence of nodes \(x_1, \ldots, x_n\).

We say that an oriented tree \(T\) defines an hypergraph \(H\) if we can associate to every hyperedge \(h \in E(H)\) an edge \(e_h \in E(T)\) and to every node \(v \in V(H)\) a directed path \(p_v\) in \(T\) such that for every \(v \in V(H)\) and \(h \in E(V)\), \(v \in h\) if and only if \(e_h\) belongs to \(p_v\). We say that \(H\) is a network hypergraph if there is an oriented tree that defines it.

Example 2. The hypergraph \(H\) with variable-set \(\{v_1, \ldots, v_6\}\) and hyperedge-set \(\{h_1, \ldots, h_5\}\) given in Figure 1a is a network hypergraph as it is defined by tree \(T\) given in Figure 1b where we have indicated, using labels on the edges, the edge in \(T\) associated to every hyperedge in \(H\). We associate to every variable \(v_i\), \(1 \leq i \leq 6\) the directed path \(s_{(i-1 \mod 2)}, r, t_{(i-1 \mod 3)}\) in \(T\). It can be readily checked that under this assignment \(T\) defines \(H\).

Sometimes, it will be convenient to assume that the tree \(T\) defining \(H\) is minimal in the sense that no tree with fewer nodes defines \(H\). Minimal trees have the nice property that every edge \(e\) in \(T\) is associated with some hyperedge of \(H\). Indeed, assume that some edge \(e = (x, y)\) is not associated to any hyperedge in \(H\), then one could find an smaller tree \(T\) defining \(H\) by contracting edge \(e\), that is, by merging \(x\) and \(y\) into a new node \(z\) that has as in-neighbours the
union of all in-neighbours of \( x \) and \( y \) and, as out-neighbours, the union of all out-neighbours of \( x \) and \( y \).

Since the vast majority of the trees defined in this paper will be oriented we shall usually drop ‘oriented’. So, unless, otherwise explicitly stated, a tree is always an oriented tree. Finally, we note that one can decide whether a given hypergraph is a network hypergraph in time \( O(e^3v^2) \) where \( e \) is the number of hyperedges and \( v \) is the number of nodes (see chapter 20 in [35] for example).

4 Restricting only the scope or the range

It has been shown by Régin [32] that the domain filtering problem for CACs is NP-hard. Still, efficient algorithms are known for some particular cases. It seems natural to start by asking which tractable subcases of the problem can be explained by considering only the scopes of the constraints. This question has a close similarity to the study of the so-called structural restrictions of the CSP (see, for example [18] for a survey) and, not surprisingly, it can be solved by applying results developed there. Indeed, it follows easily from a result of Färnqvist and Jonsson [12] that, modulo some mild technical assumptions, if one allows arbitrary ranges in constraints, then the domain filtering problem is solvable in polynomial time if and only if the hypergraph of the scopes of the constraints has bounded tree-width (see Appendix A for precise statement and the proof). This result, although delineates exactly the border between tractability and intractability, turns out to be not very useful in explaining the tractability of global constraints. This is due to the fact that global cardinality constraints defined by conjunctions of among constraints usually have constraints with large scopes and the cardinality of the scope in a constraint is a lower bound on the tree-width of its scope hypergraph.

One can also turn the attention to the range of constraints and inquiry whether there are tractable subcases of the problem that can be explained only by the range of the constraints. Here, again the response is not too useful. Indeed, it is very easy to show (see again Appendix A) that as soon as we allow some non-trivial range \( R \) (that is some range different than the empty set and than the whole domain) and arbitrary scopes in the among constraints, then the domain filtering problem becomes NP-complete.

In view of this state of affairs it is meaningful to consider families of conjunctions of among constraints that are obtained by restricting simultaneously
the scope and the range of the constraints occurring in them. This is done in the next section.

5 A flow-based algorithm

Let $I = (V, D, L, C)$ be the conjunction of among constraints. We will deal first with the case in which $D$ is a boolean, say $D = \{0, 1\}$. Hence, we can assume that every constraint $\text{AMONG}(S, R, \text{min}, \text{max})$ in $C$ satisfies $R = \{1\}$ since, if $R = \{0\}$ it can be reformulated as $\text{AMONG}(S, \{1\}, |S| - \text{max}, |S| - \text{min})$. We also assume that $L(v) = \{0, 1\}$ for every $v \in V$ since if $L(v) \neq \{0, 1\}$ we could obtain easily an equivalent instance without variable $v$.

It is easy to construct a system of linear equations whose feasible integer solutions encode the solutions of $I$. Let $v_1, \ldots, v_n$ be the variables of $I$ and let $C_j = (S_j, \{1\}, \text{min}_j, \text{max}_j)$, $j = 1, \ldots, m$, be its constraints. The system has variables $x_i (1 \leq i \leq n)$, $y_j (1 \leq j \leq m)$ and the following equations:

\[
\begin{align*}
    y_j + \sum_{v_i \in S_j} x_i &= \text{max}_j, & j = 1, \ldots, m \\
    0 &\leq y_j \leq \text{max}_j - \text{min}_j, & j = 1, \ldots, m \\
    0 &\leq x_i \leq 1, & i = 1, \ldots, n
\end{align*}
\]

which we express in matrix form as

\[
Mz = a \\
0 \leq z \leq c
\]

with $z^T = (x_1, \ldots, x_n, y_1, \ldots, y_m)$ (see Example [3]).

If $M$ is totally unimodular then one can perform domain filtering in polynomial time. Indeed, for every $v_i \in V$ and $d \in L(v)$, we might decide whether $d$ is a supported value for $v$ as follows: add equation $x_i = d$ to the system and decide whether there exists a feasible solution of its linear relaxation using a LP solver. It follows from total unimodularity (see Theorem 19.1 in [35] for example) that such a feasible solution exists if and only if $d$ is a support for $v$.

However, this approach implies invoking $O(n)$ times a LP solver, which might be too expensive to be practical, since, in addition, a propagation-based algorithm might call a domain filtering algorithm many times during its execution. To overcome this difficulty we shall require further conditions on the matrix $M$. To this end, we define the hypergraph associated to instance $I$ to be the hypergraph $H$ with $V(H) = V$ and $E(H) = \{S_j \mid 1 \leq j \leq m\}$.

Now, assume that $H$ is a network hypergraph defined by a tree $T$. In this case, one can use specific and more efficient methods like the network simplex algorithm (see for example [1]) instead of a general purpose LP solver. However, it is still possible to do better (and avoid the $O(n)$ calls to the network simplex algorithm) by transforming it into a maximum flow problem. This idea has been used in [26] to obtain a domain filtering algorithm for the SEQUENCE constraint.
More precisely, [26] deals with the particular case of network matrices defined by a directed path. Our approach draws upon [26] and generalizes it to network matrices defined by arbitrary trees. This is done as follows.

Let $P$ be the incidence matrix of $T$. That is, let $t_1, \ldots, t_{m+1}$ be an arbitrary ordering of nodes in $T$ and define $P$ to be the $((m+1) \times m)$-matrix where $P_{i,j}$ is $+1$ if edge $e_{S_j}$ starts at $t_i$, $-1$ if $e_{S_j}$ ends at $t_i$, and $0$ otherwise.

Let $r$ be a $m$-ary (column) vector and let $p$ be a path in $T$. We say that $r$ is the indicator vector of $p$ if for every $j = 1, \ldots, m$, $r_j$ is the polarity of $e_{S_j}$ with respect to $p$. The next observation follows directly from the definitions.

**Observation 1** Let $p$ be a path in $T$ and let $r$ be its indicator vector. Then, the $i$th entry, $(P r)_i$, of $P r$ is $+1$ if $t_i$ is the first node in $p$, $-1$ if $t_i$ is the last node in $p$, and $0$ otherwise.

The next two lemmas follow directly from the previous observation.

**Lemma 1.** $P$ has full rank.

**Proof.** Let $P'$ be the $(m \times m)$ matrix obtained by removing the last row (corresponding to vertex $t_{m+1}$) and consider the $(m \times m)$-matrix $Q$ such that for every $i = 1, \ldots, m$, the $i$th column of $Q$, which we shall denote as $Q_{*,i}$, is the indicator vector of the unique path in $T$ starting at $t_i$ and ending at $t_{m+1}$. It follows from Observation 1 that $P'Q$ is the identity matrix.

Then, since $P$ has full rank we can obtain an equivalent system $PMz = Pa$ by multiplying both sides of $Mz = a$ by $P$. Let $N = PM$ and $b = Pa$ (see Example 3).

**Lemma 2.** In every column of $N$ one entry is $+1$, one entry is $-1$, and all the other entries are $0$.

**Proof.** It is only necessary to show that every column, $M_{*,k}$, $k = 1, \ldots, m+n$ of $M$ is the indicator vector of some directed path in $T$. If the variable corresponding to the $k$-column is $x_i$ for some $1 \leq i \leq n$ then by construction $M_{*,k}$ is the indicator column of the path associated to $v_i$ in $T$. Otherwise, if the variable corresponding to column $k$ is $y_j$ for some $1 \leq j \leq m$ then $M_{*,k}$ is the indicator vector of the directed path containing only edge $e_{S_j}$.

Hence, matrix $N$ is the incidence matrix of a directed graph $G$. Note that, by definition, $G$ contains an edge $e_k$, $k = 1, \ldots, m+n$ for each variable $z_k$ and a node $u_j$, $j = 1, \ldots, m+1$ for each row in $N$ (that is, for every node in $T$). Define the capacity of every edge $e_k$ to be $c_k$. Then, feasible solutions of the system correspond precisely to flows where every node $u_j$ has a supply/demand specified by $b_j$ (more precisely, node $u_j$ has a demand of $b_j$ units if $b_j > 0$ and a supply of $-b_j$ units if $b_j < 0$). It is well known that this problem can be reduced to the (standard) maximum flow problem by adding new source and sink nodes $s, t$ and edges from $s$ to $u_i$ with capacity $b_j$ whenever $b_j > 0$ and from $u_j$ to $t$ with capacity $-b_j$ whenever $b_j < 0$. 
Example 3. Let $I$ be a boolean instance with variables $\{v_1, \ldots, v_6\}$ and constraints: $C_1 = \text{AMONG} \{\{v_1, v_4\}, \{1\}, 0, 1\}$, $C_2 = \text{AMONG} \{\{v_2, v_5\}, \{1\}, 0, 1\}$, $C_3 = \text{AMONG} \{\{v_3, v_6\}, \{1\}, 0, 1\}$, $C_4 = \text{AMONG} \{\{v_1, v_3, v_5\}, \{1\}, 1, 1\}$, $C_5 = \text{AMONG} \{\{v_2, v_4, v_6\}, \{1\}, 1, 1\}$.

The specific values for $M$, $a$ and $c$ of the ILP formulation of $I$ are:

\[
M = \begin{pmatrix}
1 & 0 & 0 & 1 & 0 & 0 & 1 & 0 & 0 \\
0 & 1 & 0 & 0 & 1 & 0 & 0 & 1 & 0 \\
0 & 0 & 1 & 0 & 0 & 1 & 0 & 0 & 1 \\
0 & 0 & 0 & 1 & 0 & 1 & 0 & 1 & 0 \\
0 & 0 & 0 & 0 & 1 & 0 & 1 & 0 & 1
\end{pmatrix}
\quad a = \begin{pmatrix} 1 \\ 1 \\ 1 \\ 1 \\ 1 \end{pmatrix}
\quad c^T = \begin{pmatrix} 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 \end{pmatrix}
\]

Note that since $\min_i = \max_i$ for $i = 4, 5$ we did not need to add the slack variables $y_4$ and $y_5$. The hypergraph of this instance is precisely the hypergraph $H$ in Example 2. In particular, $h_i$ is the hyperedge corresponding to the scope of constraint $C_i$ for $i = 1, \ldots, 5$. The matrix $P$ obtained from the tree $T$ defining $H$ is:

\[
T = \begin{pmatrix}
h_1 & h_2 & h_3 & h_4 & h_5 \\
t_0 & 1 & 0 & 0 & 0 \\
t_1 & 0 & 1 & 0 & 0 \\
t_2 & 0 & 0 & 1 & 0 \\
s_0 & 0 & 0 & 0 & 1 \\
s_1 & 0 & 0 & 0 & 1 \\
r & 1 & 1 & 1 & -1 & -1
\end{pmatrix}
\]

Multiplying $M$ and $c$ by $P$ we obtain:

\[
N = PM = \begin{pmatrix}
t_0 & -1 & 0 & 0 & -1 & 0 & 0 & -1 & 0 \\
t_1 & 0 & -1 & 0 & -1 & 0 & 0 & -1 & 0 \\
s_0 & 0 & 0 & 1 & 0 & 1 & 0 & 1 & 0 \\
s_1 & 0 & 0 & 0 & 1 & 0 & 1 & 0 & 1 \\
r & 1 & 1 & 1 & 0 & 0 & 0 & 0 & 0
\end{pmatrix}
\quad b = Pa = \begin{pmatrix} -1 \\ -1 \\ -1 \\ 1 \\ 1 \end{pmatrix}
\]

The feasible solutions of the previous LP correspond to the feasible flows of the network in Figure 2a where nodes $x_0, s_1$ and $r$ have a supply of one unit of flow and nodes $x_0, s_1, y_2$ have a demand of one unit of flow. Figure 2a contains the result of transforming the network in Figure 2a to a (standard) max flow problem. In both networks all edges have capacity 1.

It follows from this construction that for every $1 \leq i \leq n$ and every $d \in \{0, 1\}$, there is a solution $s$ of $I$ with $s(v_i) = d$ if and only if there is a saturating flow (that is, a flow where all the edges leaving $s$ or entering $t$ are at full capacity) such that the edge associated to $x_i$ carries $d$ units of flow. Régis 30 31 has shown that this later condition can be tested simultaneously for all $1 \leq i \leq n$ and $d \in \{0, 1\}$ by finding a maximal flow and computing the strongly connected components of its residual graph. Finding a maximal flow of a network with
Fig. 2a. Network with supplies/demands

Fig. 2b. Standard flow network obtained from (2a)

integral capacities can be done in time $O(\min(v^{2/3}, e^{1/2})e \log(v^2/e) \log u)$ using Goldberg and Rao’s algorithm [17] where $v$ is the number of vertices, $e$ is the number of edges, and $u$ is the maximum capacity of an edge. Computing the strongly connected components of the residual graph takes $O(v + e)$ time using Tarjan’s algorithm [36]. By construction, the network derived by our algorithm satisfies $e \leq n + 2m$ and $v \leq m + 1$. Furthermore, it is not difficult to see that $u \leq mn$. Indeed, note that the capacity of any edge is either some entry, $c_i$, of vector $c$ or the absolute value of some entry, $b_i$, of vector $b$. It follows directly from the definition of $c$, that all its entries are at most $n$. As for $b$, the claim follows from the fact that $b = Pa$ where, by construction, $a$ has $m$ entries where every entry is in the range $\{1, \ldots, n\}$ and every entry in $P$ is in $\{-1, 0, 1\}$.

Hence, if we define $f(n, m)$ to be $\min(m^2/3, (n + m)^{1/2}(n + m) \log(m^2/(n + m))) \log mn)$ we have:

**Lemma 3.** There is a domain filtering algorithm for conjunctions of boolean among constraints whose associated hypergraph is a network hypergraph, which runs in time $O(f(n, m))$ where $n$ is the number of variables and $m$ is the number of constraints, assuming the instance is presented as a network flow problem.

It is customary, when analyzing the time complexity of domain filtering to report, additionally, the so-called time complexity ‘down a branch of a search tree’ which consists in the aggregate time complexity of successive calls to the algorithm, when at each new call, the list of some of the variables has been decreased (as in the execution of a propagation-search based solver). It was observed again by Régin [31] that, in this setting, it is not necessary, to solve the flow problem from scratch at each call, leading to a considerable reduction in total time. Applying the scheme in [31], we obtain that the time complexity down a branch of a search tree of our algorithm is $O(n(n + m))$. We omit the details because they are fairly standard (see [31]).

There are minor variants (leading to the same asymptotic complexity) obtained by modifying the treatment of the slack variables. Here we will discuss two of them. In the first variant, used in [26], one encodes a constraint $C_j = (S_j, \{1\}, min_j, max_j)$ with two equations $y_j + \sum_{v_i \in S_j} x_i = max_j$, and $-z_j + \sum_{v_i \in S_j} x_i = min_j$ where $y_j$ and $z_j$ are new slack variables satisfying $0 \leq y_j, z_j$. This encoding produces a network that has $m$ more nodes and edges. In a second variant, one encodes a constraint $C_j$ with the equation $-y_j + \sum_{v_i \in S_j} x_i = 0$ where $y_j$ satisfies $min_j \leq y_j \leq max_j$. Under this encoding, our approach produces a network problem where, instead of having nodes
with specified supply or demand, we have edges with minimum demand. The
asymptotic time bounds in all variants are identical.

If the instance is not presented as a network flow problem then one would
need to add the cost of transforming the instance into it. However this cost
would be easily amortized as a domain filtering algorithm is invoked several
times during the execution of a constraint solver\(^2\). Furthermore, in practical
scenarios, the conjunction of among constraints will encode a global constraint
from a catalog of available global constraints. Hence, it is reasonable to assume
that the formulation of the global constraint as a network flow problem can be
precomputed.

This approach can be generalized to non-boolean domains via boolean en-
coding. The choice of boolean encoding might depend on the particula
t instance at hand but for concreteness we will fix one. The canonical booleanization (see
Example 4) of a conjunction \(I = (V, D, L, C)\) of among constraints with \(|D| \geq 3\)
is the boolean instance \((V \times D, \{0,1\}, L_b, C_b)\) where \(L_b(v,d) = \{0,1\}\) if \(d \in L(v)\)
and \(\{0\}\) otherwise, and \(C_b\) contains:

\begin{itemize}
  \item \textsc{Among}(S \times R, \{1\}, \text{min}, \text{max}) for every constraint \textsc{Among}(S, R, \text{min}, \text{max}) \in C, and
  \item \textsc{Among}(\{v\} \times D, \{1\}, 1, 1) for every variable \(v \in V\). This family of constraints are called \textit{non-empty assignment constraints}.
\end{itemize}

That is, the intended meaning of the encoding is that \((v,d) \in V \times D\) is true whenever \(v\) takes value \(d\).

We define the hypergraph \(H\) associated to \(I\) to be the hypergraph associ-
ted to the canonical booleanization of \(I\). That is, \(V(H) = V \times D\) and \(E(H)\)
contains hyperedge \(\{(v,d) | v \in S, d \in R\} = S \times R\) for every constraint \textsc{Among}(S, R, \text{min}, \text{max}) \in C, and hyperedge \(\{(v,d) | d \in D\} = \{v\} \times D\) for
every variable \(v \in V\). Thus, for arbitrary domains, we have:

**Corollary 1.** There is a domain filtering algorithm for conjunctions \((V, D, L, C)\)
of among constraints whose associated hypergraph is a network hypergraph, which
runs in time \(O(f(n, m))\) where \(n = \sum_{v \in V} |L(v)|\) and \(m = |C| + |V|\), assuming
the instance is presented as a network flow problem.

**Proof.** It just follows from observing that the canonical booleanization of in-
stance \((V, D, L, C)\) has \(n = \sum_{v \in V} |L(v)|\) variables and \(m = |C| + |V|\) constraints.

\(\blacksquare\)

### 6 Some applications

The aim of this section is to provide evidence that the kind of CACs covered
by the approach developped in Section 5 are often encountered in practice. To

\(^2\) In fact, as shown in [30,31], it is only necessary to solve the max flow problem during
the first invocation so it could be argued that a more realistic bound on the running
time of the algorithm is \(O(n + m)\).
this end, we shall revisit several families of CACs for which domain filtering have been previously introduced and show how they can solved and, in some cases generalized, using our algorithm. Furthermore, we shall compare, whenever possible, the time complexity bounds of our algorithm with other state-of-the-art algorithms for the same problem. Like other flow-based algorithms, the algorithm proposed here has very good time complexity down a branch of the search tree. However, we will only consider in our comparison the cost of calling the algorithm just once. This is due to the fact that, once the size of the network produced is under a certain threshold, the total cost down a branch of the search tree is dominated by the cost of the incremental updates and, hence, it cannot be used to assess the comparative quality of different flow-based algorithms. Furthermore, we will try to compare, whenever possible, the parameters of the obtained network flow problem (number of nodes, edges, capacities of the edges) instead of the actual running time since the latter is dependend on the choice of the max-flow algorithm. Somewhat surprisingly, in many of the cases, even if we did not attempt any fine-tuning, the network produced by the algorithm is essentially equivalent to the network produced by specific algorithms.

6.1 Disjoint constraints

As a warm up we shall consider the GCC and AllDiff constraints. We have seen in Example 1 that both can be formulated as a conjunction \((V, D, L, C)\) of among constraints of the form \(C_d = \text{AMONG}(V, \{d\}, \text{min}_d, \text{max}_d), d \in D\). Note that both have the same associated hypergraph \(H\) with node-set, \(V \times D\), and edge set \(E(H)\) containing hyperedge \(h_v = \{v\} \times D\) for every \(v \in V\), and hyperedge \(h_d = V \times \{d\}\), for every \(d \in D\).

It is not difficult to see (see Example 4) that \(H\) is defined by the tree \(T\) defined as follows: The node-set of \(T\) consists of \(\{r\} \cup V \cup D\) where \(r\) is a new node. The edge-set of \(T\) contains an edge from every \(v \in V\) to \(r\) (associated to \(h_v\)) and from \(r\) to every node \(d \in D\) (associated to \(h_d\)). Consequently, both GCC and AllDiff are solvable by our algorithm. The network for the GCC using the abovementioned tree \(T\) has \(e = O(|V||D|)\) edges, \(v = |V| + |D| + 3\) nodes, and the maximum capacity, \(u\), of an edge is at most \(|D||V|\). Hence, it follows that the total running time of our algorithm for the GCC constraint is \(O(\min(v^{2/3}, e^{1/2}) e \log(v^2/e) \log u)\). Régis’s algorithm [31] has a \(O(|V|^2|D|)\) complexity which is better when \(|V| \in O(|D|^{2/3})\) but the comparison between the two bounds is not very meaningful because it mainly reflects a different choice max flow algorithm. Indeed, the network produced by both algorithms are very similar. In particular, the network obtained using the second variant discussed after Lemma 5 is essentially the same described in [31]. The only difference is that the network obtained by our algorithm contains one extra node. In the particular case of the AllDiff constraint, [30] shows how to produce a bipartite matching problem that can be solved using specialized algorithms, such as [20], leading to a total time complexity of \(O(|V|^{3/2})\) which is better than ours.
Example 4. Consider the constraint \text{ALLDIFF}(s_0, s_1) where the list of each variable contains the following three values: $t_0, t_1, t_2$. Then, \text{ALLDIFF}(s_0, s_1) is encoded as a CAC $I$ with the following constraints: \text{AMONG}([s_0, s_1], \{t_0\}, 0, 1), \text{AMONG}([s_0, s_1], \{t_1\}, 0, 1), \text{AMONG}([s_0, s_1], \{t_2\}, 0, 1).

The canonical booleanization of $I$ has variables $[s_0, s_1] \times \{t_0, t_1, t_2\}$ and constraints $C_1 = \text{AMONG}([s_0, s_1] \times \{t_0\}, \{1\}, 0, 1), C_2 = \text{AMONG}([s_0, s_1] \times \{t_1\}, \{1\}, 0, 1), C_3 = \text{AMONG}([s_0, s_1] \times \{t_2\}, \{1\}, 0, 1), C_4 = \text{AMONG}([s_0] \times \{t_0, t_1, t_2\}, \{1\}, 1, 1), \text{and } C_5 = \text{AMONG}([s_1] \times \{t_0, t_1, t_2\}, \{1\}, 1, 1).$ Observe that this instance is, under the renaming $v_i \mapsto (s_{i-1} \mod 2, t_{i-1} \mod 3)$, the same instance than we have considered previously in Example $3$. The network flow problem that our algorithm derives for this instance (see Example $3$) is almost identical to the one derived in $31$. Indeed, the network obtained in $31$ does not have node $r$ and, instead, requires that the demand of nodes $t_0, t_1, t_2$ is at most one (instead of exactly one).

A simple analysis reveals that the same approach can be generalized to instances $(V, D, L, C)$ satisfying the following disjointment condition: for every pair of constraints $\text{AMONG}(S, R, \text{min}, \text{max})$ and $\text{AMONG}(S', R', \text{min}', \text{max}')$ in $C$, $(S \times R) \cap (S' \times R') = \emptyset$. The tractability of such instances was, to the best of our knowledge, not known before. The particular case in which $R \cap R' = \emptyset$ has been previously shown in $32$ using a different approach. The proof given in $32$ does not construct a flow problem nor gives run-time bounds so we omit a comparison.

### 6.2 Domains consisting of subsets

Consider the following generalization of our setting where in a CAC $(V, D, L, C)$ every variable $v$ must be assigned to a subset of $L(v)$ (instead of a single element). In this case, the semantics of the among constraint need to be generalized as well. Instead, we will say a constraint \text{AMONG}$(S, R, \text{min}, \text{max})$ is satisfied by a mapping $s : V \rightarrow 2^D$ if $\text{min} \leq \sum_{v \in S} |s(v) \cap R| \leq \text{max}$. To avoid confusion we shall refer to this variant of the among constraint as set among constraint.

For example, the \text{SYMMETRIC-GCC} constraint $21$ is precisely a conjunction $(V, D, L, C)$ of set among constraints of the form \text{AMONG}$(V, \{d\}, \text{min}, \text{max})$ where $d$ is a singleton which, additionally, might contain constraints of the form \text{AMONG}$(v, D, \text{min}, \text{max})$ restricting the size of the image of a variable $v$.

It is fairly easy to reduce a conjunction of set among constraints $I = (V, D, L, C)$ to a conjunction of (ordinary) among constraints over a boolean domain. Indeed, one only needs to construct the instance $(V \times D, \{0, 1\}, L_b, C_b)$ where $L_b(v, d) = \{0, 1\}$ if $d \in L(v)$ and $\{0\}$ otherwise, and $C_b$ contains \text{AMONG}(S \times R, \{1\}, \text{min}, \text{max})$ for every constraint \text{AMONG}$(S, R, \text{min}, \text{max}) \in C$. Note that the instance thus constructed corresponds exactly to the result of removing the non-empty assignment constraints to the canonical booleanization of $I$ (now regarded as a conjunction of ordinary among constraints). It is then easy to observe that if $(V, D, L, C)$ encodes a \text{SYMMETRIC-GCC} constraint then the resulting boolean instance has the same hypergraph, $H$, than the GCC constraint.
and hence, $H$ is a network matrix. The algorithm in [21] follows closely that in [31] for the GCC constraints, and, in particular, has the same time bounds. Consequently the network flow derived by our algorithm is obtained, again, by adding one extra node with small capacities in the edges to the network introduced in [21].

6.3 The sequence constraint

The Sequence constraint [6] corresponds to instances $(\{v_1, \ldots, v_n\}, D, L, C)$ with constraints $\text{AMONG}(\{v_i, \ldots, v_{i+k}\}, R, \text{min}, \text{max}), i = 1, \ldots, n - k$ for some fixed integers $\text{min}, \text{max}, k$, and fixed $R \subseteq D$. It is not difficult to see that the hypergraph of the canonical booleanization of the Sequence constraint is not a network hypergraph. However, as shown in [26] one obtains an equivalent instance with a network hypergraph using a different encoding in which for every original variable $v_i \in V$, we have a boolean variable $x_i$ which is intended to be true whenever $v_i$ takes a value in $R$ and false otherwise. Under this alternative encoding we obtain a boolean instance $I$ which consists of constraints $\text{AMONG}(\{x_i, \ldots, x_{i+k}\}, \{1\}, \text{min}, \text{max}), i = 1, \ldots, n - k$. It is shown in [26] that the hypergraph $H$ of the boolean instance $I$ obtained under this encoding satisfies the so-called consecutive-ones property which implies that $H$ is defined by a tree $T$ consisting of a single directed path. Indeed, the network flow obtained by our approach is identical to the one derived in [26] if one encodes AMONG constraints using the first variant discussed after Lemma 3. Applying Lemma 3 and noting that, in the particular case of the Sequence constraint, we have $m = O(n)$ we obtain the bound $O(n^{3/2} \log^2 n)$. By inspecting closely the proof of Lemma 3 this bound can be slightly improved (see Appendix C) to $O(n^{3/2} \log n \log \text{max})$ coinciding with the bound given in [26], which is not surprising since both networks are essentially equivalent. To the best of our knowledge $O(n^{3/2} \log n \log \text{max})$ is the best bound among all complete domain consistency algorithms for the problem, jointly with the algorithm proposed in [37] which, with time complexity $O(n^{2k})$, offers better bounds when $k \ll n$.

6.4 TFO model

The TFO model was introduced by Razgon et al. [29] as a generalization of several common global constraints. Formally, a TFO model is a triple $(V, F_1, F_2)$ where $V$ is a finite set of vertices and $F_1$ and $F_2$ are nonempty families of subsets of $V$ such that two sets that belong to the same family are either disjoint or contained in each other. Each set $Y$ in $F_1 \cup F_2$ is associated with two non-negative integers $\text{min}_Y, \text{max}_Y \leq |Y|$. A subset $X$ of $V$ is said to be valid if $\text{min}_Y \leq X \cap Y \leq \text{max}_Y$ for every $Y \in F_1 \cup F_2$. The task is to find the largest valid subset. Although the methods introduced in the present paper can be generalized to deal as well with optimization version we will consider only now the feasibility problem consisting in finding a valid subset (or report that none exists).
First, note that the existence of a valid subset in a TFO model can be formulated naturally as a satisfiability problem for a combination of among constraints. Indeed, there is a one-to-one correspondence between the valid subsets of \((V, F_1, F_2)\) and the solutions of the instance \((V, \{0, 1\}, L, C)\) where \(C\) contains the constraints \textsc{Among}(Y, \{1\}, \text{min}_Y, \text{max}_Y), Y \in F_1 \cup F_2\), and the list \(L(v)\) of every variable \(v \in V\) is \(\{0, 1\}\). The hypergraph \(H\) associated to this instance is \((V, F_1 \cup F_2)\). It follows directly from Lemmas 4 and 5 (see Appendix) that \(H\) is a network hypergraph and hence one can use our approach to decide the existence of a feasible solution of a TFO model. It turns out that the network introduced in [29] is essentially equivalent to the network flow problem that would be obtained by our approach using the second variant described after Lemma 3. It is not meaningful to compare the running time of our algorithm with that of [29] since it deals with an optimization variant.

6.5 Conjunction of among constraints with full domain

Some global constraints studied in the literature correspond to conjunctions \((V, D, L, C)\) of among constraints where the scope of every constraint is the full set \(V\) of variables. This class contains, of course, the GCC constraint and also several others, since we do not require \(R\) to be a singleton. For example, the \textsc{OrderedDistribute} constraint introduced by Petit and Régin [28] can be encoded as conjunction \((V, D, L, C)\) of among constraint where where the domain \(D\) has some arbitrary (but fixed) ordering \(d_1, \ldots, d_{|D|}\) and in every constraint \textsc{Among}(S, R, \text{min}, \text{max}), S = V\) and \(R\) is of the form \(\{d_1, \ldots, d_{|D|}\}\).

We shall show that the hypergraph of the conjunction of among constraints defining \textsc{OrderedDistribute} is a network hypergraph. Indeed, with some extra work we have managed to completely characterize all CAC instances containing only constraints with full scope that have an associated network hypergraph.

**Theorem 1.** Let \(I = (V, D, L, C)\) be a conjunction of among constraints with \(|D| \geq 3\) such that the scope of each constraint is \(V\). Then, the following are equivalent:

1. The hypergraph of the canonical booleanization of \(I\) is a network hypergraph.
2. For every pair of constraints in \(C\), their ranges are disjoint or one of them contained in the other.

In the particular case of \textsc{OrderedDistribute} constraint, the network obtained by our approach is very related to the network introduced in section (28, Section V.A). More precisely, the abovementioned network is essentially equivalent to the network that would be obtained by our approach using the second variant described after Lemma 3. However, our algorithm is far from optimal. In particular, a complete filtering algorithm with time complexity \(O(|V| + |D|)\) is given also in [28].

14
6.6 Adding new among constraints to a GCC constraint

Let \((V, D, L, C)\) be a conjunction of among constraints encoding the GCC constraint (see Example[1]) and assume that we are interested in adding several new among constraints to it. In general, we might end up with a hard instance but depending on the shape of the new constraints we might perhaps still preserve tractability. Which among constraint we might safely add? This question has been addressed by Régim [32]. In particular, [32] shows that the domain filtering problem is still tractable whenever:

(a) every new constraint added has scope \(V\) and, furthermore, the ranges of every pair of new constraints are disjoint, or
(b) every new constraint added has range \(D\) and furthermore, the scopes of every pair of new constraints are disjoint.

We can explore this question by inquiring which families of constraints can be added to an instance \((V, D, L, C)\) encoding GCC such that its associate hypergraph is still a network hypergraph. Somewhat surprisingly we can solve completely this question (see Theorem 2). This is due to the fact that the presence of the global cardinality constraint restricts very much the shape of the tree defining the hypergraph of the instance.

**Theorem 2.** Let \(I = (V, D, L, C)\) be a conjunction of among constraints containing a global cardinality constraint with scope \(V\) with \(|D| \geq 3\). Then the following are equivalent:

1. The hypergraph of the canonical booleanization of \(I\) is a network hypergraph.
2. In every constraint in \(C\), the scope is a singleton or \(V\), or the range is a singleton or \(D\). Furthermore, for every pair \(\text{AMONG}(S_1, R_1, \text{min}_1, \text{max}_1), \text{AMONG}(S_2, R_2, \text{min}_2, \text{max}_2)\) of constraints in \(C\) the following two conditions hold:
   (a) If \(S_1 = S_2 = V\) or \(S_1 = S_2 = \{v\}\) for some \(v \in V\) then \(R_1\) and \(R_2\) are disjoint or one of them is contained in the other.
   (b) If \(R_1 = R_2 = D\) or \(R_1 = R_2 = \{d\}\) for some \(d \in D\) then \(S_1\) and \(S_2\) are disjoint or one of them is contained in the other.

Note that the previous theorem covers cases (a) and (b) from [32] described at the beginning of this section. The network produced in [32] for the case (a) is essentially equivalent to the one derived by our approach using the second variant described after Lemma[3]. For the case (b) [32] does not construct a flow problem nor gives run-time bounds so we omit a comparison.

Appendix A: Tractable subcases of the domain filtering problem restricting only the scope or the range in the constraints

If $\mathcal{I}$ is a set of conjunctions of among constraints, we shall denote by $\text{DomFilter}(\mathcal{I})$ the restriction of the domain filtering problem to instances in $\mathcal{I}$. Our ultimate goal would be to characterize precisely for which sets $\mathcal{I}$, $\text{DomFilter}(\mathcal{I})$ has efficient algorithms.

The first question that we address is the following: which subcases of the problem can be explained by considering only the scopes of the constraints? The
scopes occurring in an instance can be characterized by a hypergraph. More
precisely, let \( I = (V, D, L, C) \) be a conjunction of among constraints. The scope
hypergraph of \( I \) is the hypergraph \( H \) with node set \( V(H) = V \) and that contains
an hyperedge for every scope occurring in a constraint in \( C \). Formally,
\[
E(H) = \{ S \mid \text{Among}(S, R, \text{min}, \text{max}) \in C \}
\]

Let \( \mathcal{H} \) be a (possibly infinite) set of hypergraphs. We denote by \( \text{Scope}(\mathcal{H}) \) the
collection of instances \( I \) of the domain filtering problem whose scope hypergraph
belongs to \( \mathcal{H} \). Our question can be formalized in the following manner: for which
sets, \( \mathcal{H} \), of hypergraphs, is \( \text{DomFilter}(\text{Scope}(\mathcal{H})) \) efficiently solvable? Note that
if \( I \) is an instance whose scope hypergraph \( H \) is a subhypergraph of some \( H' \in \mathcal{H} \)
then we can construct, by adding superfluous new constraints to \( I \), an equivalent
new instance whose scope hypergraph is \( H' \). Hence, we can assume that \( \mathcal{H} \) is
closed under taking subhypergraphs.

We shall solve completely this question assuming some mild technical as-
sumptions. In order to state our result we need a few definitions from graph
theory and parameterized complexity. The Gaifman graph of a hypergraph \( H \),
denoted \( \text{Gaifman}(H) \) is the graph where the node-set is \( V(H) \) and the edge-set
contains all pairs \( \{u, v\} \) such that there is an hyperedge \( h \) in \( H \) with \( \{u, v\} \subseteq h \).
A tree-decomposition of a graph \( G \) is a pair \( (T, \beta) \) where \( T \) is an (ordinary,
not oriented) tree and \( \beta : V(T) \to 2^{V(G)} \) is a mapping such that the following
conditions are satisfied:

1. For every node \( v \in V(G) \), the set \( \{ x \in V(T) \mid v \in \beta(x) \} \) is non-empty and
   connected in \( T \).
2. For every edge \( \{u, v\} \in E(G) \), there is a node \( x \in V(T) \) such that \( \{u, v\} \in \beta(x) \).

The width of a tree-decomposition \( (T, \beta) \) is \( \max \{|\beta(x)| - 1 \mid x \in V(T)\} \) and
the tree-width of \( G \) is defined to be the minimum \( w \) such that \( G \) has a tree-
decomposition of width \( w \).

We will also need some notions and basic facts from parameterized com-
plexity theory. A parameterized problem over some alphabet \( \Sigma \) is a pair \( (P, \kappa) \)
consisting of a problem \( P \subseteq \Sigma^* \) and a polynomial time mapping \( \kappa : \Sigma^* \to \mathbb{N} \),
called its parameter. A parameterized problem \( (P, \kappa) \) over \( \Sigma \) is fixed-parameter tractable if there is a computable function \( f : \mathbb{N} \to \mathbb{N} \) and an algorithm that
decides if a given instance \( x \in \Sigma^* \) belongs to \( P \) in time \( f(\kappa(x)) \cdot |x|^{O(1)} \). FPT
denotes the class of fixed-parameter tractable problems. Hence, the notion of
fixed-parameter tractability relaxes the classical notion of polynomial-time solv-
bility, by admitting running times that are exponential in the parameter, which
is expected to be small.

The analogous of NP in parameterized complexity is the class \( \text{W}[1] \) which is
conjectured to contain strictly FPT. We will omit the definition of \( \text{W}[1] \) since it
is not needed in our proofs and refer the reader to \cite{14}.

**Theorem 3.** Assume \( \text{FPT} \neq \text{W}[1] \). For every recursively class of hypergraphs
\( \mathcal{H} \), \( \text{DomFilter}(\text{Scope}(\mathcal{H})) \) is polynomial-time solvable if and only if there exists
some natural number \( w \) such that the tree-width of the Gaifman graph of every hypergraph in \( \mathcal{H} \) is at most \( w \).

**Proof.** It is well known \cite{14,15} that the set of all CSP instances whose scope hypergraph has tree-width at most \( w \) for some fixed \( w \) is solvable in polynomial time. Hence it only remains to show the ‘only if’ part. This follows from a result of Färnqvist and Jonsson \cite{12}. In order to state it, we need to introduce some background.

In the list homomorphism problem (for graphs), we are given two graphs \( G, J \) and a mapping \( L : V(G) \rightarrow 2^{V(J)} \) called list. The goal is to decide whether there exists a mapping \( h : V(G) \rightarrow V(J) \) satisfying the following two conditions:

1. \( h(v) \in L(v) \) for every \( v \in V(G) \).
2. \( (h(v_1), h(v_2)) \in E(J) \) for every \( (v_1, v_2) \in E(G) \).

Such a mapping is called a solution of \((G, J, L)\). Färnqvist and Jonsson have shown that the parameterized version of the problem (parameterized by the size of \( V(G) \)) is \( \text{W}[1] \)-hard. Indeed, the problem is \( \text{W}[1] \)-hard even if the input graph, \( G \), is guaranteed to belong to a previously fixed class of graphs, provided \( G \) has unbounded tree-width. Formally, let \( \mathcal{G} \) be a set of graphs and define \( \text{p-LHom}(\mathcal{G}, \_\_) \) to be the problem:

- **INPUT:** graphs \( G, J \) with \( G \in \mathcal{G} \), and a mapping \( L : V(G) \rightarrow 2^{V(J)} \).
- **PARAMETER:** \( |V(G)| \).
- **GOAL:** Decide whether \((G, J, L)\) has a solution.

We are finally ready to state the theorem from \cite{12} that we shall use.

**Theorem 4.** (Lemma 3 in \cite{12}) Let \( \mathcal{C} \) be a recursively class of graphs that does not have bounded tree-width. Then \( \text{p-LHom}(\mathcal{C}, \_\_) \) is \( \text{W}[1] \)-hard.

We note here that, in order to simplify the exposition, we have taken the liberty to adapt the statement in \cite{12}. We are now ready to complete our proof. Assume, towards a contradiction, that \( \mathcal{H} \) is a set of hypergraphs with unbounded tree-width such that \( \text{DOMFILTER}(\text{Scope}(\mathcal{H})) \) is solvable in polynomial time. Let \( \mathcal{G} = \{ \text{Gaifman}(H) \mid H \in \mathcal{H} \} \). It follows directly by the assumptions on \( \mathcal{H} \) that \( \mathcal{G} \) has unbounded tree-width and is recursively enumerable. We shall give an FPT algorithm for \( \text{p-LHom}(\mathcal{G}, \_\_) \).

The algorithm is as follows. Let \((G, J, L)\) be any instance of the list homomorphism problem with \( G \in \mathcal{G} \). Enumerate the hypergraphs in \( \mathcal{H} \) until finding an hypergraph \( H \in \mathcal{H} \) whose Gaifman graph is \( G \). Construct the instance \( I \) in \( \text{Scope}(\mathcal{H}) \) where the set of variables is \( V(H) = V(G) \), the domain is \( V(H) \times V(J) \), the list of every node \( v \in V(H) \) is \( \{v\} \times L(v) \), and the constraints are defined as follows:

- For every \((v_1, v_2) \in E(G)\), and for every \((a_1, a_2) \notin E(H)\), include the constraint \( \text{AMONG}(h, R, 0, 1) \) where \( h \) is any hyperedge in \( H \) containing \( \{v_1, v_2\} \) and \( R = \{(v_1, a_1), (v_2, a_2)\} \).
Note that, by construction, the scope hypergraph of $I$ is a subhypergraph of $H$ and, hence, $I$ is an instance of $\text{Scope}(H)$. Since $\text{DomFilter}(\text{Scope}(H))$ is, by assumption, solvable in polynomial time then one can also decide the satisfiability of $I$ is polynomial time. Finally, return 'yes' if $I$ is satisfiable and 'no' otherwise. Note that the time required in finding $H$ depends only on $G$ whereas the time required in constructing and solving $I$ is polynomial on the size of $(G, J, L)$. Hence, the algorithm just defined is FPT. It is easy to see that it correctly solves $(G, J, L)$. Indeed, let $s$ be any mapping $s : V(H) \rightarrow V(H) \times V(J)$ which we can write as $s(v) = (s_1(v), s_2(v))$ with $s_1 : V(H) \rightarrow V(H)$ and $s_2 : V(H) \rightarrow V(J)$. It follows directly from the construction of $I$ that $s$ is a solution of $I$ if and only if $s_1$ is the identity (formally, $s(v) = v$ for every $v \in V(H)$) and $s_2$ is a solution of instance $(G, J, L)$. Hence, $I$ is satisfiable if and only if so is $(G, J, L)$. 

It is not difficult to show, following [19], that the condition $\text{FPT} \neq \text{W}[1]$ cannot be weakened (for example by requiring, instead, only $\text{P} \neq \text{NP}$). Indeed, if $\text{FPT} = \text{W}[1]$ then there exists a family $\mathcal{H}$ of hypergraphs of unbounded tree-width such that $\text{DomFilter}(\mathcal{H})$ is polynomial-time solvable. Finally, note that the hardness part of Theorem 3 holds even for conjunctions of among constraint whose range has cardinality 2. Note, that the hardness direction does not hold any more if one requires that the among constraints have range of cardinality 1. Indeed, the $\text{ALLDIFF}$ constraint is encoded by a conjunction of among constrains whose scope hypergraph can have arbitrary large tree-width and the range of every constraint is a singleton.

Secondly, we turn our attention to the range and investigate which restrictions on the range of among constraints guarantee that the domain filtering problem is solvable in polynomial time. To this end we can define the range hypergraph in a similar way to the scope hypergraph and define, for every set $\mathcal{H}$ of hypergraphs, $\text{Range}(\mathcal{H})$ to be the set of all conjunctions of among constraints whose range hypergraph belongs to $\mathcal{H}$. The next theorem, which is straightforward, shows that all non-trivial hypergraphs give rise to hard problems.

**Theorem 5.** Assume $\text{P} \neq \text{NP}$. For every hypergraph $H$, $\text{DomFilter}(\text{Range}(\mathcal{H}))$ is polynomial-time solvable if and only every hypergraph $H \in \mathcal{H}$ has only trivial hyperedges (that is, if for every $H \in \mathcal{H}$ and every $h \in E(H)$, $h = \emptyset$ or $h = V(H)$).

**Proof.** The 'if' direction is trivial. Indeed, if the range hypergraph of an instance $I$ has only trivial hyperedges it follows that every among constraint in it is either superfluous (in the sense that it does not enforce any restriction) or unsatisfiable. For the 'only if' direction, assume that $\mathcal{H}$ has an hypergraph $H$ with a non trivial hyperedge $h$. We define a reduction from $\text{One-In-Three Sat}$ which is the following NP-complete [16] problem:

- **INPUT:** An hypergraph $J$ where all the hyperedges have cardinality 3.
- **GOAL:** Decide whether there exists some $X \subseteq V(J)$ such that $h \cap X = 1$ for every $h \in E(J)$. 

20
The reduction is as follows: given an instance $J$, of One-In-Three Sat, construct the instance $I = (V, D, L, C) \in \text{Range}(\mathcal{H})$ where $V = V(J)$, $D = V(H)$, $L(v) = V(H)$ for every $v \in V$, and $C$ contains the constraints $(S, h, 1, 1)$ for every $S \in E(J)$. It is easy to see that the range hypergraph of $I$ is $H$ and that $J$ is satisfiable if and only if so is $I$. 

Appendix B: Proofs of section 6

Basic concepts and results about network hypergraphs

If $T$ is an oriented tree and $x \in V(T)$ we denote by $T^-(x)$ (respectively $T^+(x)$) the subtree of $T$ containing all those nodes appear in some directed path ending (respectively, starting) at $x$.

A rooted tree is an oriented tree that is obtained from an undirected tree by fixing a node $r$, called the root, and orienting all the edges away from the root or all the edges towards the root.

Lemma 4. For every hypergraph $H$ the following are equivalent:

1. Every pair of hyperedges in $H$ are either disjoint or contained in each other.
2. There exists a rooted tree $T$ that defines $H$ such that the path associated to every variable ends at the root.

Furthermore, when condition (2) holds we can assume that in every edge $e = (x, y)$ associated to a minimal hyperedge of $H$, $x$ has in-degree zero.

Proof. (1 $\Rightarrow$ 2). Let $H$ be an hypergraph satisfying (1). Let $T$ be the oriented tree defined in the following way. The node-set of $T$ is $E(H) \cup \{r\}$ where $r$ is a fresh node. For every $h \in H(T)$, $T$ contains an edge from $h$ to $h'$ where $h' = r$ if $h$ is not contained in any other hyperedge of $H$ and $h'$ is the smallest hyperedge in $H$ containing $h$ otherwise. Note that $T$ has root $r$ and that if $e = (x, y)$ is an edge associated to a minimal hyperedge of $H$, then $x$ has in-degree zero. It is not difficult to verify that $T$ satisfies condition (2). (2 $\Rightarrow$ 1). Assume that $T$ is a tree satisfying condition (2). Let $h$ and $h'$ be hyperedges in $H$ and let $e_h = (x, y)$ and $e_{h'} = (x', y')$ be their associated edges in $T$. Consider three cases: (a) there is a directed path from $x$ to $x'$, (b) there is a directed path from $x'$ to $x$, (c) none of the previous holds. In case (a) it follows from the fact that the path associated to every variable ends at the root that every path containing $e_h$ contains also $e_{h'}$ and hence $h \subseteq h'$. By the same argument, case (b) implies that $h' \subseteq h$. Finally, in case (c) there is no directed path containing both $e_h$ and $e_{h'}$ and, consequently, $h \cap h' = \emptyset$.

Oriented trees can be combined by gluing some of their nodes. Formally, let $T_1$ and $T_2$ be trees and let $r_1$ and $r_2$ be nodes in $T_1$ and $T_2$ respectively. Assume, renaming nodes if necessary, that $V(T_1) \cap V(T_2) = \emptyset$. Then, the result of gluing $r_1$ and $r_2$ is obtained by, first, computing the disjoint union of $T_1$ and $T_2$ and, then, merging $r_1$ and $r_2$ into a new node $w$ that has as in-neighbours the union of all in-neighbours of $r_1$ and $r_2$ and, as out-neighbours, the union of
all out-neighbours of \( r_1 \) and \( r_2 \). It is not difficult to see that the result is again an oriented tree.

The following technical lemma, which follows directly from the definitions, will be useful.

**Lemma 5.** For \( i = 1, 2 \), let \( H_i \) be an hypergraph, let \( T_i \) be a tree defining \( H_i \) and let \( r_i \in V(T_i) \). Assume that \( V(H_1) = V(H_2) \) and that for every \( v \in V(H_1) \) the following holds: if \( v \in h_1 \cap h_2 \) with \( h_1 \in H_1 \) and \( h_2 \in H_2 \) then the last node of the path associated to \( v \) in \( T_1 \) is \( r_1 \) and the first node of the path associated to \( v \) in \( T_2 \) is \( r_2 \). Then, the result of gluing \( r_1 \) and \( r_2 \) defines \( H_1 \cup H_2 \).

**Proof.** Straightforward.

**Lemma 6.** Let \( H \) be an network hypergraph defined by tree \( T \) and let \( J \) be a subhypergraph of \( H \) with the property that for every \( a, b \in E(J) \) there exists some \( c \in J \) with \( a \cap c \neq \emptyset \) and \( b \cap c \neq \emptyset \). Then there exists an element \( r \in V(T) \) such that for every \( h \in E(J) \), \( e_h \in E(T^-(r)) \cup E(T^+(r)) \)

**Proof.** For every \( h \in H_1 \cup H_2 \), let \( e_h = (x, y) \) be its associated edge in \( T \) and let us define \( T_h \) to be the subtree of \( T \) with node-set \( V(T_h) = V(T) \cup V(T^-) \). It follows that \( V(T_a) \cap V(T_b) \neq \emptyset \) for every \( a, b \in J \). Indeed, let \( c \) be the hyperedge in \( J \) such that \( a \cap c \neq \emptyset \) and \( b \cap c \neq \emptyset \). Then both endpoints of the edge \( e_c \) associated to \( c \) belong to \( V(T_a) \cap V(T_b) \).

Next we shall use the 2-Helly property of the subtrees of a tree (see for example [5]).

**Lemma 7.** (2-Helly property of subtrees) Let \( T_1, \ldots, T_n \) be a collection of subtrees of an (undirected) tree \( T \) such that for every \( 1 \leq i, j \leq n \), \( V(T_i) \cap V(T_j) \neq \emptyset \). It follows that \( \bigcap_{1 \leq i \leq n} V(T_i) \neq \emptyset \).

Note that the 2-Helly property stated deals with undirected trees (instead of oriented trees). However it easily implies that the same property holds for oriented trees. Hence, it follows that \( \bigcap_{h \in J} V(T_h) \neq \emptyset \). To complete the proof note that any vertex \( r \in \bigcap_{h \in J} V(T_h) \) satisfies the conditions of the Lemma.

**Lemma 8.** Let \( I = (V, D, L, C) \) be a conjunction of among constraints with \( |D| \geq 3 \), let \( H \) be the hypergraph of its canonical booleanization, let \( H_1 \) be a set of at least 2 hyperedges in \( E(H) \) where every hyperedge, \( S \times R \), in \( H_1 \) satisfies \( S = V \) and let \( H_2 \) be the subset of \( E(H) \) containing, for every \( v \in V \), the hyperedge \( \{v\} \times D \). Then, if \( H \) is a network hypergraph then there exists a tree \( T \) defining \( H \) and a node \( r \in V(T) \) such that for every \( h \in H_1 \), \( e_h \in E(T^-(r)) \) and for every \( h \in H_2 \), \( e_h \in E(T^+(r)) \).

**Proof.** Assume that \( H \) is a network hypergraph and let \( T \) be a tree defining it. We shall use the following claim.

**Claim** Let \( x_1, e_1, x_2, \ldots, e_{n-1}, x_n \) be a directed path in \( T \), and let \( e_i, e_j, e_k \) such that \( e_i \) is \( i < j < k \) be different edges such two of their associated hyperedges belong to \( H_2 \) and the remaining one to \( H_1 \). Then, the edge whose associated hyperedge belongs to \( H_1 \) is \( e_j \).

22
Proof. Let \( h_i, h_j, h_k \) be the hyperedges associated to \( e_i, e_j, \) and \( e_k \) respectively and assume, towards a contradiction, that \( h_i \in H_1 \) (the case \( h_k \in H_1 \) is symmetric). Let \((v, d) \in h_i \cap h_k\) and let \( p \) be its associated path. Clearly, \( p \) contains both \( e_i \) and \( e_k \) and hence it must contain also \( e_j \) in contradiction with the fact that \( h_j \cap h_k = \emptyset \).

For every directed path \( p = x_1, \ldots, x_n \) define \( T(p) \) to be the subtree of \( T \) induced by \( V(T^+(x_1)) \cup \{x_1, \ldots, x_n\} \cup V(T^-(x_n)) \). We define \( J^- \) (resp. \( J^+ \)) to be the set containing all \( h \in H_1 \cup H_2 \) with \( e_h \in E(T^-(x_1)) \) (resp. \( e_h \in E(T^+(x_n)) \)).

The proof proceeds by showing that there exists a tree \( T \) defining \( H \) and a directed path \( p \) in \( T \) satisfying all the following properties:

1. \( e_h \in E(T(p)) \) for every \( h \in H_1 \cup H_2 \).
2. \( J^- \cap H_1 = \emptyset \) or \( J^- \cap H_2 = \emptyset \). Also, \( J^+ \cap H_1 = \emptyset \) or \( J^+ \cap H_2 = \emptyset \).
3. \( J^- \) and \( J^+ \) are non empty.
4. \( J^+ = H_2 \).

Note that if \( T \) and \( p \) satisfy (1) – (4) then \( T \) and \( r = x_n \) satisfy the Lemma.

Let us show the existence of \( T \) and \( p \) satisfying the above-mentioned properties in increasing order:

1. First, note that \( J = H_1 \cup H_2 \) satisfies the hypothesis of Lemma 4 and, hence, it follows that there exists an element \( r \in T \) such that for every \( h \in H_1 \cup H_2 \), \( e_h \) belongs to \( T^-(r) \) or \( T^+(r) \). Hence, the path \( p \) consisting of single node \( r \) satisfies (1).

2. We claim that every path \( p = x_1, \ldots, x_n \) of maximal length satisfying (1) must satisfy (2) as well. Assume, towards a contradiction, that \( a_i \in J^- \cap H_i \) for \( i = 1, 2 \) (the proof for \( J^+ \) is analogous). For every \( h \in J^- \) let \( q_h \) be a directed path in \( T \) containing \( e_h \) and ending at \( x_1 \). It follows that the last edge in \( q_{a_1} \) and \( q_{a_2} \) must be identical since otherwise there could not be a directed path containing both \( e_{a_1} \) and \( e_{a_2} \), which would imply that \( a_1 \cap a_2 = \emptyset \). Let \((y, x_1)\) be the common last edge of \( a_1 \) and \( q_h \). Then, applying the same argument it follows that \((y, x_1)\) is also the last edge of \( q_h \) for every \( h \in J^- \).

Hence, by adding \( y \) at the beginning of \( y, x_1, \ldots, x_n \) we obtain another path \( p \) satisfying (1) contradicting the maximality of \( p \).

(1, 2) \( \rightarrow \) (3). It is easy to see that every path \( p \) satisfying (1) and (2) has a subpath that satisfies, additionally, (3).

(1, 2, 3) \( \rightarrow \) (4). It follows from Claim 4 that \( J^- \cap H_2 \neq \emptyset \) or \( J^+ \cap H_2 \neq \emptyset \).

We can assume, by reversing the direction of the edges in \( T \) if necessary, that \( J^+ \cap H_2 \neq \emptyset \). Since, by (2), \( J^+ \cap H_1 = \emptyset \), in order to show (4) it is only necessary to prove that \( H_2 \subseteq J^+ \). Assume towards a contradiction that there exists \( h \in H_2 \setminus J^+ \). It follows again by Claim 4 and the fact that \( H_1 \) is nonempty that \( h \in J^- \) and hence that \( H_1 \cap J^- = \emptyset \). Let \( a = V \times A, b = V \times B \) be two different hyperedges in \( H_1 \). It follows that \( e_a \) and \( e_b \) appear in path \( p \) and we can assume w.l.o.g. that \( e_a \) appears before \( e_b \) in \( p \). We shall prove that \( B \subseteq A \). Let \( d \in B \) and let \( v \in V \) be such that \( h = \{v\} \times D \). Consider the directed path \( q \) associated to \((v, d)\). Clearly \( q \) contains \( e_a \) and \( e_b \) and hence \( q \) contains \( e_a \) as well. Hence \((v, d)\) belongs to \((V, A)\), and hence, \( d \in A \). A similar reasoning, using
now any arbitrary hyperedge in $J^+$ shows that $A \subseteq B$. Hence we have $A = B$, a contradiction. This completes the proof of (4).

\[\square\]

**Proof of Theorem 1**

Let $H$ be the hypergraph of the canonical booleanization of $I$. Define $H_1$ to be the set of all hyperedges $S \times R$ in $H$ with $S = V$. Define $H_2$ to be the hypergraph associated to the non-empty assignment constraints. That is, $H_2$ contains for every $v \in V$, the hyperedge $\{v\} \times D$. Note that $h_1 \cap h_2 \neq \emptyset$ for every $h_1 \in H_1$ and $h_2 \in H_2$.

$(1) \Rightarrow (2)$. In what follows we shall assume that $|H_1| > 1$ since otherwise (2) follows directly. Assume that $H_1$ and $H_2$ satisfy the hypothesis of Lemma 8. Then, let $T$ be the tree defining $H$ and $r$ the node in $T$ given by Lemma 8. Note that for every node occurring in any hyperedge in $H_1$, its associated path $p$ must contain some edge in $T^+(r)$ and, hence, must necessarily contain $r$ as well. Then, condition (2) follows by applying Lemma 4 to $T^-(r)$.

$(2) \Rightarrow (1)$. We note that this is a particular case of direction $(2) \Rightarrow (1)$ in Theorem 2. Still we include a proof since we think it might help the reader to understand the basic idea before embarking in the more complicated proof in 2. This direction follows easily from Lemma 3 and Lemma 5. Assume that (2) holds. Then it follows from Lemma 3 that there exists a rooted tree $T_1$ defining $H_1$ such that, additionally, the path associated to every variable in $V(H)$ ends at the root, $r_1$, of $T_1$. Also, note that every two hyperedges in $H_2$ have an empty intersection which implies again by Lemma 3 that there exists a rooted tree $T_2$ defining $H_2$ such that the path associated to every variable $v \in V(H)$ starts at the root, $r_2$, of $T_2$. Then, it follows from Lemma 5 that by gluing $r_1$ and $r_2$ in $T_1$ and $T_2$ we obtain the tree defining $H$.

**Proof of Theorem 2**

Let $H$ be the hypergraph of the canonical booleanization of $I$.

$(1) \Rightarrow (2)$. Define $H_1$ to be the set containing, for every $d \in D$, the hyperedge $V \times \{d\}$. Every such hyperedge is in $H$ because we are assuming that the instance contains a global cardinality constraint. Furthermore, define $H_2$ to be the set containing all non-empty assignment constraints. That is $H_2$ contains for every $v \in V$, the hyperedge $\{v\} \times D$. Notice that if $a = V \times \{d\}$ belongs to $H_1$ and $b = \{v\} \times D$ belongs to $H_2$ then $a \cap b$ is non empty as it contains $(v,d)$. Assume that $H$ is a network hypergraph. It follows that $H_1$ and $H_2$ satisfy the hypothesis of Lemma 8 and let $T$ be the tree defining $H$ and $r$ the vertex in $V(T)$ given by Lemma 8.

We claim that for every hyperedge $h \in H$, $e_h$ belongs to $E(T^-(r)) \cup E(T^+(r))$. Indeed, if it is not the case then there exists some hyperedge $h = S \times R$ such that
its associated edge \( e_h \) has one endpoint \( y \) in \( V(T^-(r)) \cup V(T^+(r)) \) and the other, \( x \), outside. Assume that \( y \in V(T^-(r)) \) (the case \( y \in V(T^+(r)) \) is symmetric). It follows that \( e_h = (y, x) \) since otherwise \( e_h \) would be included in \( E(T^-(r)) \). Let \( (v, d) \in S \times R \) and let \( p \) be the directed path in \( T \) associated to \( (v, d) \). This path must include \( e_h \) and also the edge associated to \( V \times \{d\} \), but this is impossible since both edges must appear with different polarity because the edge associated to \( V \times \{d\} \) belongs to \( V(T^+(r)) \).

For every \( d \in D \), let \( (x_d, y_d) \) be the edge in \( T \) associated to hyperedge \( V \times \{d\} \) and let \( T_d \) be \( T^-(x_d) \). Also, define \( T_1 \) to be the subtree of \( T \) that contains all the nodes \( x \) that belong to a path starting at \( x_d \) for some \( d \in D \) and ending at \( r \).

For every \( v \in V \), let \( (x_v, y_v) \) be the edge in \( T \) associated to hyperedge \( \{v\} \times D \) and let \( T_v \) be \( T^+(y_v) \). Also, define \( T_2 \) to be the subtree of \( T \) that contains all the nodes \( x \) that belong to a path starting at \( r \) and ending at \( y_v \) for some \( v \in D \).

Let \( (v, d) \in V \times D \) and let \( p \) be the directed path in \( T \) associated to \( (v, d) \). Clearly \( p \) must contain the edges associated to \( V \times \{d\} \) and \( \{v\} \times D \) and, hence, also \( r \). It also follows that for every hyperedge, \( h \in E(T) \), containing \( (v, d) \), \( e_h \) belongs to \( T_i \) with \( i \in \{d, v, 1, 2\} \). It follows that every edge \( e \in E(T) \) is contained in some of the trees \( T_i, i \in D \cup V \cup \{1, 2\} \) we have just defined and hence we can infer the shape of \( H \) by considering separately the shape of the hypergraphs defined by each one of the trees. Then \( (1) \Rightarrow (2) \) follows from the following lemma.

**Lemma 9.** Let \( e \) (resp. \( e' \)) be an edge in \( T \), let \( h = S \times R \) (resp. \( h' = S' \times R' \)) be the hyperedge in \( H \) associated to \( e \) (resp. \( e' \)). Then the following holds:

1. If there exists \( d \in D \) such that \( e, e' \in E(T_d) \) then \( R = R' = \{d\} \). Furthermore, \( S \) and \( S' \) are disjoint or contained one in another.
2. If \( e, e' \in E(T_1) \) then \( S = S' = V \). Furthermore, \( R \) and \( R' \) are disjoint or contained one in another.
3. If there exists \( v \in V \) such that \( e, e' \in E(T_v) \) then \( S = S' = \{v\} \). Furthermore, \( R \) and \( R' \) are disjoint or contained one in another.
4. If \( e, e' \in E(T_2) \) then \( R = R' = D \). Furthermore, \( S \) and \( S' \) are disjoint or contained one in another.

**Proof.** By symmetry we only need to prove the first two cases:

1. We first show that \( R = \{d\} \) (the same argument shows that \( R' = \{d\} \). Let \( (v, d') \) be any node in \( h \) and let \( p \) be its associated directed path in \( T \). Since \( p \) contains \( r \), it must contain the edge associated to \( V \times \{d\} \), which implies that \( d' = d \). Hence, \( R = \{d\} \). The fact that \( S \) and \( S' \) are disjoint or contained one in another follows from applying Lemma 4 to \( T_d \). Note that we use that the path associated to every node in \( V \times \{d\} \) must necessarily include \( x_d \).

2. We first show that \( S = V \) (the same argument shows that \( S' = V \). Let \( p \) be the directed path associated to any variable \( (v, d) \in S \times R \). This path contains \( x_d \) and \( r \) which implies that every path associated to a variable in \( V \times \{d\} \) contains also \( e_h \). It follows that \( V \times \{d\} \subseteq S \times R \) and, hence,
Recall from Section 6.3 that a Sequence constraint is encoded as a boolean CAC with constraints: \textsc{among}((x_i, \ldots, x_{i+k}), \{1\}, \min, \max) where \(i = 1, \ldots, n-k\) and \(\min, \max, k\) are fixed integers. Our goal is to improve the bound \(O(n^{3/2} \log^2 n)\) given in Section 6.3 to \(O(n^{3/2} \log n \log \max)\). To this end we note, inspecting the proof of Lemma 5 that in the log \(mn\) factor appearing in the function \(f(n, m)\), \(mn\) is has been obtained by bounding the quantity \(u\) (where \(u\) is the maximum capacity of the edges in the network constructed by the algorithm) by \(O(\log n)\).

We shall show that in the particular case of the Sequence constraint we can obtain a better bound. In particular, we will see that \(u \leq \max\) (and hence \(\log u \leq \log \max\)), which suffices to obtain our desired bound.

Recall the definitions of \(a, b, c, T, \text{ and } P\) from the proof of Lemma 5 and recall also that the capacity of every edge in the network constructed by our
algorithm is either an entry of vector $c$, which in the particular case of the \texttt{SEQUENCE} constraint, is either $max - min$ or 1 (and, hence, at most $max$), or the absolute value of an entry of vector $b = Pa$. In the particular case of the \texttt{SEQUENCE} constraint, all entries of $a$ are $max$. Also, recall that the tree $T$ defining a the hypergraph of a \texttt{SEQUENCE} constraint is a directed path which implies that every row of $P$ has at most one $+1$, at most one $-1$, and the rest of entries are 0. It follows that every entry in $b$ is in $\{-max, 0, max\}$ and we are done.
