Neutrino emission in processes of breaking and formation of neutron and proton Cooper pairs is calculated within the Larkin-Migdal-Leggett approach for a superfluid Fermi liquid. We demonstrate explicitly that the Fermi-liquid renormalization respects the Ward identity and assures the weak vector current conservation. The systematic expansion of the emissivities for small temperatures and nucleon Fermi velocity, \( v_F, i = n, p \) is performed. Both neutron and proton processes are mainly controlled by the axial-vector current contributions, which are not strongly changed in the superfluid matter. Thus, compared to earlier calculations the total emissivity of processes on neutrons paired in the 1S\(_0\) state is suppressed by a factor \( \approx (0.9-1.2) v_F^2 \). A similar suppression factor \( \sim v_F^2 \) arises for processes on protons.

I. INTRODUCTION

In minutes/hours after the birth a neutron star cools down to a temperature \( T \sim \text{MeV} \) via a neutrino transport to the surface and then becomes transparent for neutrinos. Hereafter during \( \sim 10^5 \) yr the cooling is determined by emissivity of neutrinos produced in direct reactions \( \bar{\nu}_e + p \rightarrow n + \nu_e, \bar{\nu}_e + n \rightarrow p + \nu_e \). For such temperatures neutrons and protons in the neutron star interior are highly degenerate. Therefore the rate of the neutrino production is suppressed by the reaction phase space, the stronger, the more nucleons are involved.

The most efficient are one-nucleon processes, e.g., \( n \rightarrow p e^+ \nu \), called direct Urca (DU) reactions. Their emissivity is \( \varepsilon_{DU} \sim 10^{27} \times T^{8}_9 (n/n_0)^{2/3} \theta(n - nC) \frac{\epsilon_{\text{cm}^3 s}}{\epsilon_{\text{erg}}}, \) see [3], where \( T_9 = T/10^9 \text{K} \), \( n \) is the nucleon density measured in units of the nuclear matter saturation density \( n_0 \). The DU processes are operative only when the proton fraction exceeds a critical value of 11–14%. Equations of state constructed from realistic nucleon-nucleon interactions, like Urbana-Argonne one [4], show that this condition is fulfilled only at very high densities. This implies that the DU processes may occur only in most heavy neutron stars, e.g., with masses \( \sim 2 M_\odot \) for the equation of state [5], where \( M_\odot = 2 \times 10^{33} \text{g} \) is the solar mass. At \( n \sim n_0 \) the proton fraction is typically about 3–5%, cf. Fig. 2 in Ref. [4].

In the absence of the DU processes, most efficient become two-nucleon reactions, e.g., \( nn \rightarrow npe^+ \nu \), called modified Urca processes (MU) with the emissivity \( \varepsilon_{MU} \sim 10^{21} \times T^{8}_9 (n/n_0)^{2/3} \frac{\epsilon_{\text{cm}^3 s}}{\epsilon_{\text{erg}}}, \) cf. [10]. Note the smaller numerical prefactor and the higher power of the temperature for the emissivity of the two-nucleon processes compared to the DU emissivity. In-medium change of the nucleon-nucleon interaction in the spin-isospin particle-hole channel due to pion softening may strongly increase the two-nucleon reaction rates, which, nevertheless, in all relevant cases remain significantly smaller than that for the DU [2, 11]. The nucleon bremsstrahlung reactions, like \( nn \rightarrow n \nu n \nu \) (nB) and \( pp \rightarrow p \nu p \nu \) (pB), have an order of magnitude smaller emissivity than MU.

At low temperatures the nucleon matter is expected to undergo a phase transition into a state with paired nucleons [12]. The neutron superfluidity and/or proton superconductivity take place below some critical temperatures \( T_{c,n} \) and \( T_{c,p} \), respectively, which depend on the density. At densities \( n < (2-4) n_0 \) neutrons are paired in the 1S\(_0\) state and in the 3P\(_2\) state at higher densities. Protons are paired in 1S\(_0\) state for densities \( n \lesssim (2-4) n_0 \). Paring gaps, \( \Delta_i \), are typically \( \sim (0.1-1) \text{MeV} \) and depend crucially on details of the interaction in the particle-particle channel, see Fig. 5 in [13].

The gap in the energy spectrum significantly reduces the phase space of the nucleon processes roughly by the factor \( \exp(-\Delta/T) \) for the one-nucleon DU process and \( \exp(-2\Delta/T) \) for two-nucleon processes. However, even with inclusion of the nucleon pairing effects the DU rate is large enough that the occurrence of these processes would lead to an unacceptably fast cooling of a neutron star in disagreement with modern observational soft X-ray data [2, 13, 14]. This statement has been tested with gaps varying in a broad band allowed by different microscopic calculations. Certainly, DU processes could be less efficient if one kept gaps finite also at high densities.

*present address
Microscopic calculations do not support this possibility. Thus, according to the recent analysis the DU processes most probably will not occur in typical neutron stars with masses in the range of 1.0–1.5 $M_\odot$, based on the cooling and the population syntheses scenarios [13, 14, 15].

The superfluidity allows for a new mechanism of neutrino production associated with Cooper pair breaking or formation (PBF), e.g., the reaction $n \rightarrow n\nu\bar{\nu}$ and $p \rightarrow p\nu\bar{\nu}$, where one of the nucleons is paired. For $1S_0$ neutron pairing the PBF emissivity was evaluated first in [16] in the Bogolyubov $\psi$-operator technique and then in [17, 18] within the Fermi-liquid approach.

The proton PBF emissivity was estimated in [17] with account for in-medium renormalization of the nucleon weak-interaction vertex due to strong interactions. Mixing of electromagnetic and weak interactions through the electron–electron-hole loop can additionally change the proton vertex [19, 20]. There are also relativistic corrections to the axial-vector coupling vertices of the order $v^2_{F,i} \approx \frac{m_i^2}{2\pi T} T/m_i$ in the superfluid system the nucleon Green function no- tionally differs from the free one, the vector-current vertex must get corrections even if no other interaction between quasiparticles is included. Additional anomalous vector-current vertices disregarded in previous calculations must be properly accounted for. These corrections cancel exactly the vector-current contributions to the neutrino emissivity for zero neutrino momenta, cf. [17].

Assuming that the axial-vector current contributes only little to the PBF emissivity, Ref. [27] claimed that the PBF emissivity calculated in [16, 17, 22] is to be suppressed by factor $\sim v^2_{F,n}/20 \sim 10^{-3}$ for $n \sim n_0$ for neutrons and by $\sim 10^{-7}$ for protons in the case of $1S_0$ pairing. Such a large reduction of the neutron and proton PBF emissivities could significantly affect previous results on the neutron star cooling dynamics. Ref. [31] revises results [27] applying expansion in $q^2$ parameter and putting $v_{F,n} = 0$. Ref. [31] claims that suppression factor for the neutron PBF emissivity is $\sim T/m^*$, where $m^*$ is the nucleon effective mass. This would reduce the neutron PBF emissivity by the factor $\sim 5 \times 10^{-3}$ for temperatures $T \approx 0.5 T_{c,n}$, cf. Fig. 5 in [31].

Refs. [27, 31] used the convenient Nambu-Gorkov matrix formalism developed to describe metallic superconductors [32, 33]. The price paid for the convenience is that the formalism does not distinguish interactions in the particle-particle and particle-hole channels. Such an approach is, generally speaking, not applicable to the strongly interacting matter present in neutron stars. In the nucleon matter at low temperatures the $nn$ and $pp$ nucleon-nucleon interactions in the particle-particle channel are attractive, whereas in relevant particle-hole channels they are repulsive [17, 29, 30]. The adequate formalism was developed by Larkin and Migdal for Fermi liquids with pairing at $T = 0$ in Ref. [34] and generalized then by Leggett for $T \neq 0$ in Ref. [35].

In the present paper using Larkin-Migdal-Leggett formalism we analytically calculate neutrino emissivity from the superfluid neutron star matter with the $1S_0$ neutron-neutron and proton-proton pairing. Both normal and anomalous vertex corrections are included. We explicitly demonstrate that the Fermi-liquid renormalization [34] respects the Ward identity and vector current conservation. Our final estimations of neutron and proton PBF emissivities differ from those in [27, 31]. We find that the main term in the emissivity $\sim \frac{v^2_{F,i}}{T^3}$ follows from the axial-vector current, whereas the leading term in the emissivity from the vector current appears only at the $v^2_{F,i}$ order, as
where \(l_\mu = \bar{\nu}_\gamma (1 - \gamma_5) \nu \) is the lepton current and \(V^\mu = g_V \bar{\Psi}_\gamma \gamma^\mu \Psi_i \) and \(A^\mu = g_A \bar{\Psi}_\gamma \gamma_5 \gamma^\mu \Psi_i \) stand for nucleon (neutron or proton) vector and axial-vector currents with nucleon bi-spins \(\Psi_i \). The coupling constants are \(g_V = g_V^{(a)} = g_V^{(p)} = c_V = 1 - 4 \sin^2 \theta_W \approx 0.04 \) and \(g_A^{(a)} = g_A^{(p)} = -g_A^{(a)} = g_A = 1.26 \). The Fermi constant is \(G \approx 1.2 \times 10^{-5} \) GeV\(^{-2} \).

For the non-relativistic nucleons \(V^\mu \approx \psi_i(p')\{1 - (\vec{p}' + \vec{p})/2m\} \psi_i(p)\) and \(A^\mu \approx \psi_i(p')\{\sigma(\vec{p}' + \vec{p})/2m\} \sigma \psi_i(p)\), where \(\sigma = (\sigma_1, \sigma_2, \sigma_3)\) are the Pauli matrices acting on nucleon spinors \(\psi_i\), and \(\vec{p}'\) and \(\vec{p}\) are outgoing and incoming momenta, \(m\) is the mass of the free nucleon, cf. \[36\].

Neutrino emissivity for one neutrino species can be calculated as
\[
\varepsilon_{\nu\beta} = \frac{G^2}{8} \int \frac{d^3q_1}{(2\pi)^3} \frac{d^3q_2}{(2\pi)^3} \omega \epsilon \hat{f}_B(\omega) 2 \Im \chi(q),
\]
where \(q = (\omega, \vec{q}) = q_1 + q_2, q_{1,2} = (\omega_{1,2}, \vec{q}_{1,2})\) are 4-momenta of outgoing neutrino and antineutrino, \(\hat{f}_B(\omega) = 1/(\exp(\omega/T) - 1)\) are Bose occupations, and \(\Im \chi\) is the imaginary part of the susceptibility of the nucleon matter to weak interactions, i.e. the Fourier-transform of the current-current correlator \(\langle [V^\mu(x) - A^\mu(x)](V^\nu(y)) \rangle\), for weak processes. The sum in \[2\] is taken over the lepton spins.

According to the optical theorem \(\Im \chi\) can be expressed as the sum squared matrix elements of all available reactions with all possible intermediate states, \(\sum |M|^2\). A particular contribution to \(\sum |M|^2\) can be also calculated within the Bogolubov \(\psi\)-operator approach for a given form of the nucleon-nucleon interaction, as it has been done in Refs. \[10\] \[22\]. In this approach, however, an account of further in-medium modifications of nucleon propagators and interaction vertices is obscured by a danger of double counting. The Green-function technique for Fermi liquid \[29\] \[30\] is more suitable for such extensions as it was demonstrated in \[11\] \[17\]. We will follow the Green-function approach for superfluid Fermi liquids \[29\] \[34\]. As a simplification we will focus on the low temperature limit \(T \ll \Delta\). The temperature dependence enters through nucleon occupation factors \(\propto e^{-\Delta/T} (1 + O(T^2/\Delta^2))\) and also as \(1 + O(T^2/\Delta^2)\) corrections in the low-temperature expansion of standard Fermi integrals, when the high energy region \(\epsilon \gg \Delta\) is dominating in the integrals. Since the boson occupation factor \(f_B\) in \[2\] generates already the leading exponent \(e^{-2\Delta/T}\) we can evaluate \(\Im \chi\) for \(T = 0\), see also discussion below.

**A. Neutrino emissivity**

The weak neutrino-neutron and neutrino-proton interactions on neutral currents are described by the effective low-energy Lagrangian
\[
\mathcal{L} = \frac{G}{2\sqrt{2}} \sum_{i=p,n,} (V^\mu - A^\mu) l_\mu,
\]
where \(l_\mu = \bar{\nu}_\gamma (1 - \gamma_5) \nu \) is the lepton current and \(V^\mu = g_V \bar{\Psi}_\gamma \gamma^\mu \Psi_i \) and \(A^\mu = g_A \bar{\Psi}_\gamma \gamma_5 \gamma^\mu \Psi_i \) stand for nucleon (neutron or proton) vector and axial-vector currents with nucleon bi-spins \(\Psi_i\). The coupling constants are \(g_V^{(a)} = g_V^{(p)} = c_V = 1 - 4 \sin^2 \theta_W \approx 0.04 \) and \(g_A^{(a)} = g_A^{(p)} = -g_A^{(a)} = g_A = 1.26 \). The Fermi constant is \(G \approx 1.2 \times 10^{-5} \) GeV\(^{-2} \).

For the non-relativistic nucleons \(V^\mu \approx \psi_i(p')\{1 - (\vec{p}' + \vec{p})/2m\} \psi_i(p)\) and \(A^\mu \approx \psi_i(p')\{\sigma(\vec{p}' + \vec{p})/2m\} \sigma \psi_i(p)\), where \(\sigma = (\sigma_1, \sigma_2, \sigma_3)\) are the Pauli matrices acting on nucleon spinors \(\psi_i\), and \(\vec{p}'\) and \(\vec{p}\) are outgoing and incoming momenta, \(m\) is the mass of the free nucleon, cf. \[36\].

Neutrino emissivity for one neutrino species can be calculated as
\[
\varepsilon_{\nu\beta} = \frac{G^2}{8} \int \frac{d^3q_1}{(2\pi)^3} \frac{d^3q_2}{(2\pi)^3} \omega \epsilon \hat{f}_B(\omega) 2 \Im \chi(q), \tag{2}
\]
where \(q = (\omega, \vec{q}) = q_1 + q_2, q_{1,2} = (\omega_{1,2}, \vec{q}_{1,2})\) are 4-momenta of outgoing neutrino and antineutrino, \(\hat{f}_B(\omega) = 1/(\exp(\omega/T) - 1)\) are Bose occupations, and \(\Im \chi\) is the imaginary part of the susceptibility of the nucleon matter to weak interactions, i.e. the Fourier-transform of the current-current correlator \(\langle [V^\mu(x) - A^\mu(x)](V^\nu(y)) \rangle\), for weak processes. The sum in \[2\] is taken over the lepton spins.

**II. GENERAL EXPRESSIONS: EMISSIVITY, GREEN FUNCTIONS AND PAIRING GAPS**

### A. Neutrino emissivity

The weak neutrino-neutron and neutrino-proton interactions on neutral currents are described by the effective low-energy Lagrangian
\[
\mathcal{L} = \frac{G}{2\sqrt{2}} \sum_{i=p,n,} (V^\mu - A^\mu) l_\mu, \tag{1}
\]

### B. Nucleon Green functions and pairing gaps

The nucleon Green function for the interacting system in a normal state ("n.s.") i.e. without paring, is given by the Schwinger-Dyson equation, which in the momentum representation reads
\[
\hat{G}_{n.s.}(p) = \hat{G}_0(p) + \hat{G}_0(p) \hat{\Sigma}_{n.s.}(p) \hat{G}_{n.s.}(p),
\]

with \(\hat{G}_0(p) = G_0(\epsilon, \vec{p}) \mathbf{1} = \mathbf{1}/(\epsilon - \epsilon_\nu + i0^+ \text{sgn} \epsilon)\), where \(\mathbf{1}\) is the unity matrix in the spin space. All information on the interaction is incorporated in the nucleon self-energy \(\hat{\Sigma}_{n.s.}\), being a functional of the Green functions \(\hat{G}_{n.s.}\). In absence of the spin-orbit interaction the full Green function is also diagonal in the spin space, i.e.
\[
\hat{G}_{n.s.} = G_{n.s.} \mathbf{1}.
\]

For strongly interacting systems, like dense nucleon matter, the exact calculation of \(G_{n.s.}\) is extremely difficult task. However, for strongly degenerate nucleon systems at temperatures, \(T\), much less than the neutron and proton Fermi energies, \(\epsilon_{F,i}, i = n, p\), fermions are only slightly excited above the Fermi see. So, the full Green function of the normal-state is given by the sum of the pole term and a regular part:
\[
G_{n.s.}(p) = \frac{a}{\epsilon - \epsilon_\nu + i0^+ \text{sgn} \epsilon} + G_{\text{reg}}(p), \tag{3}
\]

where the excitation energy is counted from the nucleon chemical potential \(\mu \), \(\epsilon_\nu = p^2/(2m^n) - \mu\), \(\mu \approx \epsilon_F = p_F^2/(2m^*)\) for low temperatures under consideration, \(p_F\) is the Fermi momentum. The effective mass and the non-trivial pole residue are determined by the real part of the self-energy, as \(\text{a}^{-1} = 1/(\partial \Re \Sigma_{n.s.}/\partial \epsilon)\) and \(1/m^* = a/(1 + 2\partial \Re \Sigma_{n.s.}/\partial p^2)\). The subscript "F"
indicates that the corresponding quantities are evaluated at the Fermi surface ($\epsilon, \epsilon_p \to 0$). According to Ref. [29] only the pole part of $G_{\text{n.s.}}$ is relevant for the description of processes happening in a weakly excited Fermi system. The regular part can be absorbed by the renormalization of the particle-particle and particle-hole interactions at the Fermi surface. The quantities $m^*$ and $a$ can be expressed through the Landau-Migdal parameters characterizing the fermion interaction at the Fermi surface at zero energy-momentum transfer. The imaginary part of the self-energy, $\Sigma_{\text{n.s.}}$, can be omitted in the pole term of the Green function [3] in the low-temperature limit (quasiparticle approximation).

In a system with pairing a new kind of processes such as transition of a particle into a hole and a condensate pair and vice versa become possible. The one-particle one-hole irreducible amplitudes of such processes can be depicted as [34]

$$-i \hat{\Delta}^{(1)} = -i \hat{\Delta}, -i \hat{\Delta}^{(2)} = -i \hat{\Delta}^{(2)}.$$

Besides the "normal" Green functions shown by the "thick" line $i \hat{G} = \bullet$, one introduces "anomalous" Green functions $i \hat{F}^{(1)} = \bullet$, and $i \hat{F}^{(2)} = \bullet$. The full normal and anomalous Green functions are related by Gor'kov equations

$$\hat{G}(p) = \hat{G}_{\text{n.s.}}(p) + \hat{G}_{\text{n.s.}}(p) \hat{\Delta}^{(1)}(p) \hat{F}^{(2)}(p),$$

$$\hat{F}^{(2)}(p) = \hat{G}_{\text{n.s.}}^h(p) \hat{\Delta}^{(2)}(p) \hat{G}(p).$$

The second equation involves the normal-state Green function of the hole (superscript "h"), which in the absence of a spin-orbit interaction is simply $i \hat{G}_{\text{n.s.}}^h(p) = i \hat{G}_{\text{n.s.}}(-p) = \bullet$. In the case of the $1S_0$ pairing the spin structures of the anomalous Green functions and the transition amplitudes [4] are simple: $\hat{\Delta}^{(1)} = \hat{\Delta}^{(2)} = \Delta$ and $\hat{\Gamma}_{\text{F}} = \hat{\Gamma}^{(2)} = F \sigma_2$. Eqs. [5] are to be completed by the equation for the amplitude $\hat{\Delta}(p)$

$$[\hat{\Delta}(p)]_b = \int \frac{d^d p'}{(2\pi)^d} \left[ \bar{V}(p,p') \right]_{ab} \hat{G}(p') \hat{\Delta}^{(1)}(p') \hat{G}_{\text{n.s.}}(p') \frac{d}{c}.$$

where $\bar{V}$ stands for a two-particle irreducible potential, which determines the full in-medium particle-particle scattering amplitude. The potential $\bar{V}$ can be separated in the scalar and spin-spin interactions defined as

$$[\bar{V}]_{bd} = V_{V}(i\sigma_2)^b_d(i\sigma_2)^c_d + V_{A}(i\sigma_2)^b_d(\bar{\sigma} i\sigma_2)^c_d.$$

Solution of the Gor'kov equations [4] is straightforward. The relevant pole parts of Green functions are

$$G(p) = \frac{a (\epsilon + \epsilon_p)}{\epsilon^2 - E_p^2 + i\delta \text{ginc}}, F(p) = \frac{-a \Delta}{\epsilon^2 - E^2_p + i\delta \text{ginc}},$$

where $E_p = \epsilon_p + \Delta^2$. Integrations over the internal momenta in fermion loops, e.g., over $p'$ in [6], involve energies far off the Fermi surface. One may renormalize [29, 30] the interaction $\bar{V} \to \bar{V}^z$ in such a manner that integrations go over the region near the Fermi surface and only the quasiparticle (pole) term in the Green function [7] is operative. Advantage of the Fermi-liquid approach is that all expressions enter renormalized amplitudes rather than the bare potentials. For $|p'| \simeq p_F \simeq |p|$, the effective interaction amplitude is a function of the angle between $\hat{p}$ and $\hat{p}'$ only. The amplitude in the particle-particle channel is parameterized as

$$[\hat{\Gamma}_\text{ac}]_{bd} = \Gamma_{\text{F}}^{\xi}(\vec{n}, \vec{n}') (i\sigma_2)^b_d(i\sigma_2)^c_d + \Gamma_{\text{F}}^{\xi}(\vec{n}, \vec{n}')(i\sigma_2 \bar{\sigma})^c_d(\bar{\sigma} i\sigma_2)^b_d,$$

and the interaction in the particle-hole channel is

$$[\hat{\Gamma}_\text{ac}]_{bd} = \Gamma_{\text{F}}^{\xi}(\vec{n}, \vec{n}') \delta^c_d \delta^b_a + \Gamma_{\text{F}}^{\xi}(\vec{n}, \vec{n}') (\bar{\sigma}^c_d \sigma^b_a).$$

Here and below $\vec{n} = \vec{p}/|\vec{p}|$ and $\vec{n}' = \vec{p}'/|\vec{p}'|$. Superscript "ac" indicates that the amplitude is taken for $|\vec{q}| \nu_F | \ll \omega$ and $\omega \ll \epsilon_F$, where $\omega$ and $\vec{q}$ are transferred energy and momentum. Amplitudes $\Gamma_{\text{F}}^{\xi}, \Gamma_{\text{F}}^{\xi}$ are expanded in the Legendre polynomials.

Integrating over the internal momenta in loops we can separate the part accumulated in the vicinity of the Fermi surface $\int \frac{d^d p'}{(2\pi)^d} \approx \int \frac{d^d p}{4\pi} \times \int d\Phi_p$ with $\int d\Phi_p = \rho \int_{-\infty}^{\infty} \frac{d\epsilon_p}{2\pi} \int_{-\infty}^{\infty} d\epsilon_p \rho = \frac{m^2 \rho}{\pi^2}$ being the density of states at the Fermi surface. After the Fermi-liquid renormalization [6] reduces to

$$\Delta(\vec{n}) = -A_0 \left( \Gamma_{\text{F}}^{\xi}(\vec{n}, \vec{n}') \Delta(\vec{n}')) \right),$$

where we denoted $\langle ... \rangle = \int \frac{d^d \vec{n}}{4\pi} \langle ... \rangle$ and $\xi \sim \epsilon_F$. One usually determines the gap suppressing $\xi \approx \epsilon_F$.

## III. CURRENT-CURRENT CORRELATOR, EQUATIONS FOR VERTICES, AND VECTOR CURRENT CONSERVATION

### A. Current-current correlator

Applying theory of Fermi liquids with pairing [29, 34] we can present contributions to the susceptibility $\chi$ in terms of the diagrams

$$-i \chi = \bullet + \bullet + \bullet + \bullet.$$

Here dash line relates to the Z-boson coupled to the neutral lepton currents, vertices on the left are the bare vertices following from the Lagrangian [1]. The right-hand-side vertices $\hat{\tau}, \hat{\tau}_h, \hat{\tau}^{(1)}$ and $\hat{\tau}^{(2)}$ are the full vertices determined by the diagrams shown in Fig. 1. The blocks in Fig. 1 correspond to the two-particle irreducible interaction in the particle-particle channel, $\Gamma_{\text{F}}^{\xi}$, and the particle-hole irreducible interaction in the particle-hole channel,
\[ \chi_a = \text{Tr} \int \frac{d^4 p}{(2\pi)^4} \hat{\tau}_a^\omega \left\{ \hat{G}_+ \hat{\tau}_a^\omega \hat{G}_- + \tilde{F}_+^{(1)} \hat{\tau}_a^\omega \tilde{F}_-^{(2)} + \hat{G}_+ \hat{\tau}_a^{(1)} \tilde{F}_-^{(2)} + \tilde{F}_+^{(1)} \hat{\tau}_a^{(2)} \tilde{F}_-^{(2)} \right\}, \quad a = V, A. \]  

Here and below we use the short-hand notations \( G_\pm = G(p \pm q/2) \) and the analogous one for the \( F_\pm \) Green functions. All left vertices in \( \bar{\tau}_a^\omega \) are the \"bare\" vertices, \( \tau_a^0 \), after the Fermi-liquid renormalization \[ \tau_a^\omega = \left[ 1 + \Gamma_0 \right] (G_+ G_-)^{-1} \tau_a^0, \]  which involve the particle-hole effective interaction, \( \Gamma_0 \), integrated with off-pole parts of the Green functions \( (G_+ G_-)^{-1} = \lim_{q \to 0} \int \frac{d^4 p}{(2\pi)^4} G_+ G_- \), and \( \tau_a^0 \) follows from \( \bar{\tau}_a^\omega \). The difference between \( \tau_a^0 \) and \( \tau_a^\omega \) can be cast \( \text{in terms of a local charge of the quasi-particle} \quad e_a = a \frac{\tau_a^\omega}{\tau_a^0}. \) Then

\[ \bar{\tau}_V = g_V \left( \tau_{V,0} l_0 - \bar{\tau}_{V,1} \hat{l} \right), \quad \tau_{V,0}^\omega = \frac{e_V}{a} \bar{\tau}_V, \quad \tau_{V,1}^\omega = \frac{e_V}{a} \hat{v}. \]  

For the vector current \( e_V = 1 \) and the vertices \( \tau_{V,0}^\omega \) and \( \tau_{V,1}^\omega \) satisfy the Ward identity \( \omega \tau_{V,0} - \bar{q} \tau_{V,1} = G_{n.s.} \).\( -1 \). The local charge for the axial-vector current differs from the unity varying in different parameterizations as \( e_A \approx 0.8 - 0.95 \), as it follows from studies of the Gamov-Teller transitions in nuclei, see \( \text{29, 38, 39} \) and references therein.

B. Larkin-Migdal equations for full vertices

Consider first one sort of nucleons, e.g., neutron. At the Fermi surface the full vertices \( \bar{\tau}_V, \bar{\tau}_A^h, \bar{\tau}_A^{(1)} \) and \( \bar{\tau}_A^{(2)} \) can be treated as functions of out-going momentum \( \hat{q} \) and the nucleon Fermi velocity \( \hat{v} = v_F \hat{n}, \hat{n} = \hat{n}/p \). Their general structures are

\[ \tau_V = g_V \left( \tau_{V,0} l_0 - \bar{\tau}_{V,1} \hat{l} \right), \quad \tau_{V,0}^\omega = g_V \left( \tau_{V,0} l_0 + \bar{\tau}_{V,1} \hat{l} \right), \quad \tau_{V,1}^\omega = -g_V \left( \tau_{V,0} l_0 - \bar{\tau}_{V,1} \hat{l} \right) i \sigma_2, \quad \tau_A = -g_A \left( \bar{\tau}_{A,1} \hat{\sigma} l_0 - \bar{\tau}_{A,0} \hat{\sigma} \hat{l} \right), \]  
\[ \tau_A^h = -g_A \left( -\bar{\tau}_{A,1} \hat{\sigma} \hat{l} l_0 - \bar{\tau}_{A,0} \hat{\sigma} \hat{l} \right), \quad \tau_A^{(1)} = +g_A \left( \bar{\tau}_{A,1} \hat{\sigma} l_0 - \bar{\tau}_{A,0} \hat{\sigma} \hat{l} \right) i \sigma_2, \quad \tau_A^{(2)} = -g_A i \sigma_2 \left( \bar{\tau}_{A,1} \hat{\sigma} l_0 - \bar{\tau}_{A,0} \hat{\sigma} \hat{l} \right). \]  

Superscript \"T\" denotes matrix transposition.

As follows from the diagrammatic representation of Fig.1 the full vertices obey Larkin-Migdal equations \( \text{34} \):
where \( \alpha = V, A \) and \( P_{V,0} = -P_{V,1} = -P_{A,0} = P_{A,1} = 1 \). In order to write the one set of equations for both vector and axial-vector weak currents we introduced a new notation for the effective interaction \( \Gamma_{\alpha}^{\omega,\xi} = \Gamma_{0}^{\omega,\xi} \), if \( \alpha = V, A \), and \( \Gamma_{\alpha}^{\omega,\xi} = \Gamma_{1}^{\omega,\xi} \), if \( \alpha = A \). Functions \( L, M, N \), and \( O \) are defined as

\[
\begin{align*}
L(n, q; p) & = \int d\Phi_p \left[ G_{G +} - (G_{G -})^\omega - F_+ F_- \right] \\
M(n, q) & = \int d\Phi_p \left[ (G_{G +})^\omega \theta(\xi - \epsilon_p) + F_+ F_- \right] \\
N(n, q) & = \int d\Phi_p \left[ (G_{G +})^\omega \theta(\xi - \epsilon_p) + F_+ F_- \right] \\
O(n, q; p) & = -\int d\Phi_p \left[ G_{G +} F_- + F_+ G_{G -} \right] \\
\end{align*}
\]

(13)

Expressions (14), (15) are derived for \( L \). Generalization of expression for \( L \) requires introduction of one more temperature dependent integral besides \( g \). Such expressions were derived by Leggett in [29]. As follows from these expressions there arises an essential simplification in the limit of low temperatures, \( T \ll \Delta \). We exploit the fact that to calculate the PBF emissivity we need only imaginary part of the current-current correlator \( \Im \chi \). Since \( \omega > 2\Delta \) for the PBF kinematics, the emissivity is exponentially suppressed by \( e^{-\Delta/T} \) stemming from the Bose occupation factor \( f_B(\omega) \) in (2). Therefore, we may take \( \Im \chi \propto \Im g(T = 0) \) since it is already multiplied by the term vanishing for \( T \to 0 \).

Not accounted temperature corrections in \( \Im \chi \) prove to be \( \sim 1 + O(e^{-\Delta/T}(1 + T^2/\Delta^2)) \) in (2). The latter term follows from the expansion of Fermi integrals when the integration goes over energy regions far from the Fermi surface. Such corrections are small in the limit \( T \ll \Delta \) and we omit them.

Using vertices \((11,12)\) in (10) the correlators \( \chi_V \) and \( \chi_A \) can be expressed as

\[
\begin{align*}
\chi_V(q) & = g_{V}^{2} \left\langle (\tilde{l}_0 - \tilde{v} \tilde{I}) (\tilde{l}_0^{\dagger} \chi_{V,0}(\tilde{n}, q) - \tilde{N}_{V,1}(\tilde{n}, q) \tilde{I}^{\dagger}) \right\rangle_{\tilde{n}} \\
\chi_A(q) & = g_{V}^{2} \left\langle (\tilde{l}_0 \tilde{v} - \tilde{I}) (\tilde{l}_0^{\dagger} \chi_{A,0}(\tilde{n}, q) - \chi_{A,1}(\tilde{n}, q) \tilde{I}^{\dagger}) \right\rangle_{\tilde{n}} \\
\chi_{a,0}(\tilde{n}, q) & = L(\tilde{n}, q; P_{a,0}) \tilde{r}_{a,0}(\tilde{n}, q) + M(\tilde{n}, q) \tilde{r}_{a,1}(\tilde{n}, q). \\
\end{align*}
\]

C. Solution for vector and axial-vector parts of the current-current correlator

It is natural to expect that first and higher Legendre harmonics of \( \Gamma_{0,1}^{\omega,\xi}(\tilde{n}, \tilde{n'}) \) are smaller than the zeroth ones due to the centrifugal factor [29]. This allows us to retain only zero harmonics \( \Gamma_{0,1}^{\omega,\xi}(\tilde{n}, \tilde{n'}) = \Gamma_{0,1}^{\omega,\xi} = \text{const} \), expressed through dimension-less Landau-Migdal parameters as [29] \( \Gamma_{0,1}^{\omega,\xi} = f^{\omega,\xi}/(a^2 \rho(n)) \) and \( \Gamma_{1,0}^{\omega,\xi} = g^{\omega,\xi}/(a^2 \rho(n0)) \). The values of parameters are extracted from the analysis of atomic nucleus experiments [29, 38, 39] or in some approximations can be calculated starting from a microscopic nucleon-nucleon interaction [29]. Actually, in isospin asymmetric matter \( f^\omega \) and \( g^\omega \) are different for interactions between two neutrons \( (f_{nn}, g_{nn}) \), two protons \( (f_{pp}, g_{pp}) \) and neutron and proton \( (f_{np}, g_{np}) \). Note that values \( f^\omega, g^\omega \) are necessarily positive, the requirement of the stability of the nucleon matter, whereas corresponding values in the particle-particle channel \( f^\xi, g^\xi \) are negative, otherwise there would be no 1S0 pairing. In this respect our derivations differ from those which do not distinguish interactions in particle-hole and particle-particle channels and use Nambu-Gorkov formulations with one bare potential \( V < 0 \) in our case.

For the angular-independent amplitudes (only zeroth harmonics are included) the Larkin-Migdal equations [13] get simple solutions:

\[
\begin{align*}
\tau_{a,0}(q) & = \gamma_{a}(q; P_{a,0}) \tilde{r}_{a,0}(q), \\
\gamma_{a}^{-1}(q; P) & = 1 - \Gamma_{a}^{\omega} \left\langle L(\tilde{n}, q; P) \right\rangle_{\tilde{n}}, \\
L(\tilde{n}, q; P) & = L(\tilde{n}, q; P) - \frac{\left\langle O(\tilde{n}, q; P) \right\rangle_{\tilde{n}}}{\left\langle N(\tilde{n}, q) \right\rangle_{\tilde{n}}} M(\tilde{n}, q), \\
\tilde{r}_{a,0}(q) & = -\frac{\left\langle O(\tilde{n}, q; P_{a,0}) \right\rangle_{\tilde{n}}}{\left\langle N(\tilde{n}, q) \right\rangle_{\tilde{n}}} \tau_{a,0}(q). \\
\end{align*}
\]

We have exploited here the relation \( 1 = -\Gamma_{0}^{\xi}(A_0) \) following from the gap equation [3]. Although integrals
in (13) do not produce terms $\propto \vec{v}$ for constant $\Gamma^\omega \xi$, the vector vertices $\vec{x}_a$ and $\vec{r}_{a,1}$ gain new terms proportional to $\vec{q}$, thus, $\vec{r}_{a,1}(\vec{n}, q) = \vec{r}_{a,1}^{(q)}(\vec{n}, q) + \vec{n}_q \delta_{a,1}^{(q)}(\vec{q})$ and $\vec{x}_a(\vec{n}, q) = \vec{x}_a^{(q)}(\vec{q})$ where $\vec{n}_q = \vec{q}/|\vec{q}|$ and

$$\begin{align*}
\vec{r}_{a,1}^{(q)}(\vec{q}) &= \gamma_\alpha(q; P_{a,1}) \Gamma^\alpha_n \vec{L}(\vec{n}, q; P_{a,1}) (\vec{n}_q \vec{n}_q), \\
\vec{x}_a^{(q)}(\vec{q}) &= - \frac{\langle \vec{n}_q | \vec{x}_a(q; P_{a,1}) | \vec{n} \rangle}{\langle \vec{n} | \vec{n}_q \rangle} = - \frac{(\vec{n}_q \vec{n}_q)}{\langle \vec{n} | \vec{n}_q \rangle}.
\end{align*}$$

With (14-17) we cast $\chi_a^\mu = (\omega = 0, \vec{x}_a, \vec{n}, q)$ as

$$\begin{align*}
\chi_a(\vec{n}, q) &= \gamma_\alpha(q; P_{a,0}) \vec{L}(\vec{n}, q; P_{a,0}), \\
\tilde{\chi}_a(\vec{n}, q) &= \vec{v}_\gamma_\alpha(q; P_{a,1}) \vec{L}(\vec{n}, q; P_{a,1}) + \delta \chi_a(\vec{n}, q), \\
\delta \chi_a(\vec{n}, q) &= \frac{M(n')}{\langle N(n', q) \rangle} - \gamma_\alpha(q; P_{a,1}) (\vec{n} - \vec{n}_q),
\end{align*}$$

$$\begin{align*}
\delta \chi_{a,1}(\vec{n}, q) &= \frac{M(n')}{\langle N(n', q) \rangle} - \gamma_\alpha(q; P_{a,1}) (\vec{n} - \vec{n}_q), \\
\delta \chi_{a,1}(\vec{n}, q) &= \frac{M(n')}{\langle N(n', q) \rangle} - \gamma_\alpha(q; P_{a,1}) (\vec{n} - \vec{n}_q).
\end{align*}$$

Here $\gamma_\alpha$ are precisely those nucleon-nucleon correlation factors that have been introduced in [17]. They depend on Landau-Migdal parameters in the particle-hole reaction channels.

D. Vector current conservation

Now we note that in order to verify that the correlator of the vector current $\chi_{V}^\mu$ supports the current conservation. First we note that there are convenient relations

$$\begin{align*}
\langle \vec{L}(\vec{n}, q; P) - \vec{L}(\vec{n}, q; P_{a,0}) \rangle &= 0, \\
\langle \omega \vec{L}(\vec{n}, q; \pm 1) - \vec{L}(\vec{n}, q; \mp 1) (\vec{q} \vec{q}^* \vec{v}) \rangle &= 0, \\
\langle q \delta (\vec{x}_a(\vec{n}, q)) \rangle &= \gamma_\alpha(q; P_{a,1}) (\vec{q} \vec{q}^* \vec{v}), \\
\langle \vec{q} \vec{q}^* \vec{v} \rangle (\omega \vec{L}(\vec{n}, q; +1) - \vec{L}(\vec{n}, q; -1) - \vec{q} \delta (\vec{x}_a(\vec{n}, q)) \rangle &= \vec{q}^2 a_n \omega/m^*.
\end{align*}$$

These relations help us to establish important properties of the vector current correlators [15]:

$$\begin{align*}
\langle \omega \chi_{V,0} - \vec{q} \vec{q} \vec{V} \rangle \omega/m^* &= \gamma_\alpha(q; +1) \gamma_\alpha(q; -1) \omega \Gamma_{V}^\alpha, \\
\langle \vec{L}(\vec{n}, q; +1) \rangle (\vec{L}(\vec{n}, q; -1)) &= \langle \vec{L}(\vec{n}, q; +1) \rangle (\vec{L}(\vec{n}, q; -1)) = 0.
\end{align*}$$

We use here expansion of $\vec{L}$ and $\vec{L}$ in the series for $[\vec{q}] \vec{v}_\omega / \omega \ll 1$:

$$\begin{align*}
\vec{L}(\vec{n}, q; +1) &= \frac{\vec{y} \vec{y}}{1 - \vec{y} \vec{y}} + \vec{g} \vec{g}^* (\vec{y} \vec{y} - \vec{y} \vec{y}) + O(\gamma^5), \\
\vec{L}(\vec{n}, q; -1) &= \frac{\vec{y} \vec{y}}{1 - \vec{y} \vec{y}} - \vec{g} \vec{g}^* (\vec{y} \vec{y} + \vec{y} \vec{y}) + O(\gamma^5).
\end{align*}$$

IV. NEUTRINO EMISSION VIA NEUTRON PBF

After correlators (13) are established it remains to take the sum over the lepton spins and integrate over the leptonic phase space in (3). The latter can be easily done with the help of the Landau integral [11]:

$$\int \frac{d^3 q_1}{(2\pi)^3} \frac{d^3 q_2}{(2\pi)^3} \sum \left\{ \mu \nu \delta(\mu - \nu) \right\} \delta(4)(q_1 + q_2 - q) = \frac{1}{48 \pi^5} (q_n q_n - \vec{q} \vec{q} + q_n^2) \theta(\omega) \theta(\omega - q_n^2).$$
Now the neutrino emissivity (2) can be cast as
\[
\epsilon_{\nu\nu} = \epsilon_{\nu\nu,V} + \epsilon_{\nu\nu,A}
\]
\[
\epsilon_{\nu\nu,a} = \frac{G^2}{8} g_\nu^2 \int_0^\infty d\omega \omega f_B(\omega) \int_0^\omega \frac{d\omega}{4\pi} \frac{\kappa_a}{\omega^2}
\]
\[
\kappa_a = \int \frac{d^4q_1}{2\omega_1} \frac{d^4q_2}{2\omega_2} \langle \hat{q}^4 \rangle (q_1 + q_2 - q)
\]
\[
\times \frac{3}{4\pi} \sum \chi_a(q). \tag{26}
\]
In $\kappa_a$ the sum is taken over the lepton spins. Shortening notations we introduced in (24) effective couplings $g_\nu^2 = e_a g_\theta$. The particular normalization of the quantity $Q_a$ is chosen so that for $Q_a(\omega) = Q^0(\omega)$ with
\[
Q^{(0)}(\omega) = -\rho \Im g(\omega^2/4\Delta^2) \tag{27}
\]
we obtain expression for the neutron PBF emissivity
\[
\epsilon_{\nu\nu}^{(0n)} = \frac{4\rho n}{15\pi^3} G^2 \Delta_n^2 \frac{I(\Delta_n)}{T}, \quad I(z) = \int_1^{\infty} \frac{dy}{\sqrt{y^2-1}} e^{-2yz} \tag{28}
\]
which coincides with the old result [16, 17] after the replacement $e^{-2yz} \rightarrow \frac{1}{e^{y+1}+1}$. From now on we restore, where it is necessary, subscripts ”n” or ”p” to distinguish neutron and proton PBF processes, respectively.

A. Emissivity on vector current

For the vector current we have
\[
\kappa_V = \Im \langle \hat{q}^2 \langle \chi_{V,0}(\vec{n}, q) \rangle_{\vec{n}} + \langle \langle \hat{q}^2 \rangle \langle \chi_{V,1}(\vec{n}, q) \rangle_{\vec{n}}
+ (\omega^2 - q^2) \langle \vec{v} \chi_{V,1}(\vec{n}, q) \rangle_{\vec{n}}
- \omega \langle \hat{q} \cdot \vec{v} \rangle \chi_{V,0}(\vec{n}, q) \rangle_{\vec{n}} - \omega \langle \vec{v} \chi_{V,1}(\vec{n}, q) \rangle_{\vec{n}} \rangle. \tag{29}
\]
Using relations (18) and (20) we can simplify (29) as
\[
\kappa_V = \langle \hat{q}^2 - \omega^2 \rangle \Im \langle \chi_{V,0}(\vec{n}, q) \rangle_{\vec{n}} - \langle \vec{v} \chi_{V,1}(\vec{n}, q) \rangle_{\vec{n}} \tag{30}
\]
Both scalar and vector components in (30) are of the order $v_F^4$,
\[
\Im \langle \chi_{V,0}(\vec{n}, q) \rangle \approx -\frac{4q^4 v_F^4}{45w_4} a^2 \rho \Im g(\frac{\omega^2}{4\Delta^2}) > 0,
\]
\[
\Im \langle \vec{v} \chi_{V,1}(\vec{n}, q) \rangle \approx -\frac{2q^2 v_F^4}{9w_4} a^2 \rho \Im g(\frac{\omega^2}{4\Delta^2}) > 0.
\]
We have put $\gamma_V \rightarrow 1$ since $\gamma_V \simeq 1 + O(f_{\nu n}^2 v_F^4)$.

Note that the first term in (30), $\Im \chi_{V,0}$, would give a negative contribution to $Q_V$. Only due to the presence of the vector component of the vertex, second term in (30), the full expression for the reaction probability becomes positive. This is because we used Ward identities, which impose relations between zero- and vector components. However, if one keeps in (29) only the first term related to the zero-th component of the vertex and drops other terms, as it was done in early works, the expression for the reaction probability would be also positive.

Finally in terms of $Q_V$ we get
\[
Q_V \simeq \frac{4}{81} v_F^4 Q^{(0n)}(\omega). \tag{31}
\]
Finally for the neutron PBF emissivity on the vector current we obtain (for one neutrino flavor)
\[
\epsilon_{\nu\nu}^{PBF} \simeq \epsilon_{\nu\nu}^{(0n)} g_V^2 \frac{4}{81} v_F^4. \tag{32}
\]

Note that in spite of Ref. [27] used approximation $\omega \ll \Delta_n$, which is not fulfilled in PBF case, our expression [32] only slightly deviates from the corresponding result obtained in [27].

Authors of Ref. [31] calculated the susceptibility $\chi_V$ including only the zero-th component, $\chi_{V,0}$, for $v_\nu = 0$, performing an expansion for small $\vec{q}$. They found the leading term $\propto \frac{8\pi^2}{3} g_\nu^2$. However, it has the opposite sign (see (48) in [31]) to the second term, $\propto 1_{PB}$, in (40), that would yield reaction probability in case, if bare vertices were used. Note also that the key equations (35,38-45) in [31] differ from Larkin-Migdal equations (14) (for $T \ll \Delta$ as supposed in [31], and for $v_\nu = 0$ as assumed in [31]). As it follows from (14) and (16) our expression for $(\mathcal{L}(\vec{n}, q, +1))_{\vec{n}} \propto q^2 v_F^{2n}$, vanishes, if $v_F \sim 0$, although $q^2/m^* \sim 0$ term was present in the original loop integrals.

B. Emissivity on axial-vector current

Now we focus on the process going on the axial-vector current. Then
\[
\kappa_A = \Im \langle \hat{q}^2 \langle \hat{v} \chi_{A,1}(\vec{n}, q) \rangle_{\vec{n}} + (3\omega^2 - 2q^2) \langle \chi_{A,0}(\vec{n}, q) \rangle_{\vec{n}}
- \omega \langle \hat{q} \hat{v} \rangle \chi_{A,0}(\vec{n}, q) \rangle_{\vec{n}} - \omega \langle \hat{v} \hat{q} \rangle \chi_{A,0}(\vec{n}, q) \rangle_{\vec{n}} \rangle. \tag{33}
\]
The last two crossing terms in the squared brackets cannot be eliminated. Keeping only terms $\propto v_F^2$ we cast (33) as
\[
\kappa_A = \Im \langle \hat{q}^2 v_F^2 \langle \mathcal{L}(\vec{n}, q; +1) \rangle_{\vec{n}} + (3\omega^2 - 2q^2) \langle \mathcal{L}(\vec{n}, q; -1) \rangle_{\vec{n}}
- \omega \langle \hat{v} \hat{q} \rangle \mathcal{L}(\vec{n}, q; -1) \rangle_{\vec{n}} \rangle \approx -a^2 \rho v_F^2 \hat{q}^2 [1 + (1 - \frac{2}{3} \frac{q^2}{\Delta^2}) - \frac{2}{3}] \Im g(\frac{\omega^2}{4\Delta^2}). \tag{34}
\]
As in case with the vector current, simplifying we could put $\gamma_A = 1$ since $\gamma_A \simeq 1 + O(g_{nn}^2 v_F^4)$. 

The contribution of the axial-vector current to the neutrino emissivity is determined by
\[
Q_A^4(\omega) \simeq \left( 1 + \frac{11}{21} - \frac{2}{3} \right) v_F^2 n Q^{(0n)}(\omega). \tag{35}
\]

Second term in round brackets of (35) has been mentioned already in Ref. [22] and then recovered in Ref. [22]. Our coefficient (11/21) is twice larger than that presented in those works. We notice that the integral \(I_q/2 = (u'v - v'u)^2\), where \(u\) and \(v\) are coefficients of the Bogolyubov transformation, is in Ref. [22] twice as large as that in Ref. [22]. In agreement with the former evaluation, we arrive at the coefficient 11/21 rather than at 11/42, as presented in Ref. [22]. The first term in (35) (for \(m^* = m\)) is the same, as in Ref. [22], which calculated this relativistic correction for the first time. The factor \(\left(1 - \frac{2}{3}\right)\) is twice as large as that in Ref. [22], where main contribution was due to the vector interaction of protons in this case. The factor \(\frac{1}{21}\) does not arise in our calculations, since the mass renormalization is performed everywhere, including the vertices. Otherwise the Ward identity would not hold for the renormalized "bare" vertex \(\tau_{p\mu}\). The third term related to the time-space component product was not considered before.

Finally for the neutron PBF emissivity on the axial-vector current we obtain (for one neutrino flavor)
\[
\epsilon_{\nu\nu,A}^{n_{PBF}} \simeq \frac{6}{\pi} g_A^2 v_F^2 \epsilon_{\nu\nu}^{(0n)} \times (\text{net mass term}). \tag{36}
\]

The resulting emissivity is the sum of contributions and Ref. [22],
\[
\epsilon_{\nu\nu}^{n_{PBF}} = \epsilon_{\nu\nu,V}^{n_{PBF}} + \epsilon_{\nu\nu,A}^{n_{PBF}} \simeq \epsilon_{\nu\nu}^{n_{PBF}} \times (\text{net mass term}). \tag{37}
\]

The axial-vector term, being \(\propto v_F^2\), is now the dominating contribution. Thus, the ratio of the emissivity of the neutron PBF obtained here to the emissivity calculated in Ref. [22], where main contribution was due to the vector current, is
\[
R(n_{PBF}) = \frac{\epsilon_{\nu\nu,V}^{n_{PBF}}}{\epsilon_{\nu\nu}^{n_{PBF}}} \geq \frac{6}{\pi} g_A^2 v_F^2 \epsilon_{\nu\nu}^{n_{PBF}} = F_n v_F^2. \tag{38}
\]

For \(n = n_0 = 0.17 \text{ fm}^{-3}, m^* = 0.8 m\), we estimate \(F_n \simeq 0.9 - 1.2, v_F/n \simeq 0.36\) and \(R \simeq 0.12 - 0.15\). For \(n = 2n_0, m^* = 0.7m\), \(R\) increases up to 0.24–0.32. This is in drastic contrast with estimations \(R(n_{PBF}) \sim 10^{-3}\) in Ref. [27] (being actually valid only for the rate of partial vector current contributions, rather than for the full emissivities) and \(R(n_{PBF}) \simeq 5 \cdot 10^{-3}\) obtained in Ref. [31].

V. NEUTRINO EMISSION VIA PROTON PBF

Now we turn to the proton PBF processes. If protons were the only particles in the neutron star medium, we could use the results obtained above for the neutron PBF and just replace \(g_{\nu\nu}^{(n)} \rightarrow g_{\nu\nu}^{(p)} = \epsilon_{\nu\nu}, v_F/n \rightarrow v_F, f_{nF} \rightarrow f_{pF} \) and \(g_{nn} \rightarrow g_{pp}, \epsilon_{a}^{n} \rightarrow \epsilon_{a}^{p}\).

A. Emissivity on vector current

Since the bare vertex yields now \(g_{\nu\nu}^{(p)} = \epsilon_{\nu\nu}^2 \simeq 0.002\) compared to \(g_{\nu\nu}^{(n)} = 1\) in the neutron case one could naively think that the emissivity of the proton PBF process on the vector current is suppressed by a factor \(10^{-3}(\Delta_p/\Delta_n)^{13/2} \epsilon^2(\Delta_p - \Delta_n)/T\) compared to the emissivity of the neutron PBF process. For imaginary purely proton matter we would find in the vector channel
\[
\epsilon_{\nu\nu,V} \simeq \epsilon_{\nu\nu}^{(0p)} c_F^2 \frac{4}{81} \epsilon^2 \times (\text{net mass term}). \tag{38}
\]

In addition to that the emissivity is already suppressed in the vector channel by factor \(\frac{1}{20} v_F^2\), Leinson and Perez [27] found extra suppression. They included interaction of protons via photons. This produces new contributions to the susceptibility \(\chi\) of the following type
\[
\tau_{\nu,0} \rightarrow \frac{\tau_{\nu,0}}{\epsilon_{C}(q)} \times (\text{net mass term}). \tag{40}
\]

Dotts assume infinite summation of the bubble chains with all four types of the vertices shown in Fig. 2. The wavy line is the dressed photon Green function. Simplifying, Ref. [27] used the static Coulomb potential instead. To illustrate the origin of differences in our estimations with those in Ref. [27] we will use the same approximations. Effectively the summation leads to the replacement
\[
\tau_{\nu,0} \rightarrow \frac{\tau_{\nu,0}}{\epsilon_{C}(q)} \times (\text{net mass term}) \tag{40}
\]

where \(\epsilon_{C}(q) \simeq 1 + \omega_{pl}/\omega^2\) is the dielectric constant, \(\omega_{pl}^2 = 4 \pi e^2 n_p/m^*\) is the proton plasma frequency with \(e^2 = 1/137\). Setting \(m^* = m, \omega \simeq 2\Delta, (\omega \simeq 2\Delta + O(T)\) for the PBF processes), \(\Delta \simeq 1.767\text{eV}\) and \(T_c \simeq 1\text{ MeV}\) for \(x_p = n_p/n \sim 0.03\) at \(n = n_0\), cf. Fig. 2 of Ref. [27], we obtain \(\epsilon_{C}(q) \simeq 1 + 0.3 \sim 1\) in disagreement with estimation of Ref. [27], where applying their result to the neutron star matter authors put \(n_p = n_0\) and \(\omega \simeq T_c\) that resulted in the estimation \(\epsilon_{C}(q) \sim 10^2\). Thus, a suppression factor \(< 10^{-6}\) of the emissivity of the proton PBF process quoted in Ref. [27] is misleading. Note that correction of the vertex [40] affects only the process on the vector current, since photon is the vector particle.

For the neutron star matter, the replacement [40] is not sufficient, since protons are embedded into the electron liquid of the same concentration and into a much more dense neutron liquid. Renormalization of the weak vector interaction of protons in this case can be taken into account, if we replace the bare coupling \(g_{\nu\nu}^{(p)}\) as follows
\[
\epsilon_{\nu\nu,0} \rightarrow \frac{\tau_{\nu,0}}{\epsilon_{C}(q)} \times (\text{net mass term}). \tag{40}
\]
Dots stand for other graphs not shown explicitly, like $\Delta(1232)n$-loop correction terms, etc. Simplifying, we ignore these rather small correction terms. The second graph has been incorporated in [2, 17] that results in the shift

$$c_V \to c_V - f_{nn}^{-1}(n_0)rL_{nn}\gamma(f_{nn}^w),$$

where $\gamma^{-1}(f_{nn}^w) = 1 - f_{nn}^{-1}(n_0)rL_{nn}$ and $L_{nn} = (L(\vec{n}, q; q = 0))_{\vec{n}}/a^2 = \rho(\vec{q} \vec{v}/(\omega - \vec{q} \vec{v}))_{\vec{n}}$ is the Lindhard function. This correction (although $\propto v_n^2$) leads to the strong enhancement of the tiny bare vertex. A numerically larger correction comes from the electron–electron-hole polarization term (the third graph). Such a possibility has been discussed in [19] for the process of a possible massive photon decay and then it was taken into account in the proton PBF emissivity in [20]. Altogether these corrections can be incorporated to the resulting expression for the emissivity of the proton PBF process with the help of the replacement, cf. [21],

$$c_V^2 \to F_p \simeq c_V^2 \left[ f_{nn}^w rL_{nn}\gamma(f_{nn}^w) + 0.8C_{ve} \right]^2.$$  

Here $C_{ve} = 1$ is the electron weak vector coupling. Thus we find

$$\epsilon_{\nu\nu,V}^{PBF} \simeq \epsilon_{\nu\nu,V}^{(0p)} F_p \frac{4}{\sqrt{1}} v_F^4 \nu_F.$$  

where the pre-factor $F_p \sim 1$. Finally we obtain an estimate

$$R_{p/n} = \frac{\epsilon_{\nu\nu,V}^{PBF}}{\epsilon_{\nu\nu,V}^{PBF}} \simeq x_p^{4/3} \left( \frac{\Delta_p}{\Delta_n} \right)^{13/2} e^{2(\Delta_n - \Delta_p)/T}.$$  

The ratio $R_{p/n}$ is sensitive to the values of the proton and neutron gaps as functions of density, $\Delta_{n,p}(n)$, the proton fraction $x_p$, and the temperature $T$.

B. Emissivity on axial-vector current

Now we consider axial-vector channel. Photon exchange does not contribute in this channel. The main correction to the vertex comes from the iteration of the $nn$-loops:

$$\epsilon_{\nu\nu,A}^{PBF} \simeq \epsilon_{\nu\nu,A}^{(0p)} \frac{6}{7} v_A^2 v_F^2.$$  

We conclude

$$\epsilon_{\nu\nu}^{PBF} = \epsilon_{\nu\nu,V}^{PBF} + \epsilon_{\nu\nu,A}^{PBF} \simeq \epsilon_{\nu\nu,V}^{PBF}.$$  

For the ratio $R[p/n]$ we find

$$R[p/n] = \frac{\epsilon_{\nu\nu,V}^{PBF}}{\epsilon_{\nu\nu,A}^{PBF}} \simeq \frac{\epsilon_{\nu\nu,V}^{PBF}}{\epsilon_{\nu\nu,A}^{PBF}} \sim x_p^{4/3} \frac{1}{\Delta_n} e^{(\Delta_n - \Delta_p)/T}.$$  

The ratio $R[p/n]$ is sensitive to the choice of pairing gaps, temperature and the proton fraction $x_p$ and can be both $\lesssim 1$ and $\gtrsim 1$.

VI. CONCLUSIONS

In this paper we re-calculated neutrino emissivity via neutron and proton pair breaking and formation processes. We used Larkin-Migdal-Leggett Fermi-liquid approach to strongly interacting systems with the pairing. Compared to the Nambu-Gorkov formalism, the Larkin-Migdal-Leggett approach allows for different interactions in the particle-particle and the particle-hole channels, as it is the case for nuclear matter.

To be specific we focused our discussion on the $1S_0$ pairing. We support statement of [27] that medium effects essentially modify vector current vertices. Only the careful account of these effects allows to fulfill the Ward identity and to protect conservation of the vector current. Compared to the emissivity calculated in [16] the partial contribution to the emissivity on the neutron vector current proved to be dramatically suppressed, roughly by a factor $\sim 0.1 \times v_{F,n}^2$, $v_{F,n}$ is the neutron Fermi velocity, cf. [27]. A similar suppression factor arises for the partial contribution to the emissivity on the proton vector current, provided one replaces neutron Fermi velocity by the proton Fermi velocity. Electron–electron-hole and neutron–neutron-hole polarization effects play a crucial role in the latter estimation. Proton–proton-hole polarization effects are suppressed (these statements are at variance with the estimations in [27]).

The dominating contribution to the neutron and proton pair breaking and formation emissivity comes from the weak axial-vector current. Finally, the neutron pair breaking and formation emissivity proves to be suppressed compared to that of [16] by a factor $\sim 0.12-0.15$ at nuclear saturation density and $\sim 0.24-0.32$ at twice nuclear saturation density. For the proton pair breaking and formation the emissivity deviates only by a factor close to unity from the expression used previously in [22]. These our findings differ from those in [27, 31], where authors concluded that the neutron and proton pair breaking and formation emissivities are dramatically suppressed. Modifications of the neutron and proton pair breaking and formation reaction rates that we have found are probably not strong enough to essentially influence
on the values of surface temperatures of neutron stars computed previously.

One may rise the question how much emissivity of other relevant neutrino processes might be changed, if medium effects in presence of nucleon pairing are correctly included. Although we did not perform corresponding cumbersome calculations let formulate our conjectures:

In the reactions with charged currents, as the direct Urca and the modified Urca processes, the transferred neutrino energy is \( \omega \simeq \mu_e = p_{F,\rho} \gg 2\Delta \). Therefore the anomalous Green functions are taken in the limit \( \omega \gg 2\Delta \). In this limit \( g \)-function tends to zero (as it follows from the corresponding asymptotic in (13)). Effects of normal correlations and pion softening were evaluated in [2, 11, 17], resulting in significant enhancement of two-nucleon reaction rates. Specifics of the superfluid matter manifest themselves in reactions with charged currents mainly through the phase-space suppression factors.

The two-nucleon bremsstrahlung processes going on the neutral currents are similar to the pair breaking and formation reactions. In a normal phase the emissivities are governed by the axial-vector current [10]. Thereby, we do not expect a strong suppression of these rates in a superfluid phase except the natural phase-space suppression estimated in previous works. As in the case of the two-nucleon reactions going on charged currents, nucleon short-range correlations and pion softening significantly influence the reaction rates, cf. [2, 11].

Our findings are relevant also for calculations of the quark-pair breaking and formation processes and other quark propagation processes in the color-superconducting medium, which use bare-loop results, e.g. see Refs. [43, 44]. Note that since the pairing superconducting medium, which use bare-loop results, and other quark propagation processes in the color-superconductors can be rather large, \( 2\Delta \gg \mu_e \), both reaction rates on neutral and charged currents (Urca) might be affected. Ref. [20] considered neutrino scattering off breaking pairs in color-flavor-locked medium within the Nambu-Gorkov formalism. However, they included only the zero-th component of the vertex, and their expressions for the current-current correlator in the non-relativistic limit do not coincide with the Larkin-Migdal-Leggett expressions that we have reproduced above.

An interesting observation was made recently in Ref. [45]. A natural explanation of the super-burst igniton would require a strong suppression of the neutron pair breaking and formation emissivity for low baryon densities. For \( n \sim 10^{12} \text{ g/cm}^3 \) we estimate a suppression factor as \( \sim 0.1 \times (n/n_0)^{2/3} \sim 0.003 \).

Another relevant issue is related to absorption and scattering processes of low-energy (\( \omega \lesssim \text{few MeV} \)) neutrinos and antineutrinos on nuclei. In absence of the electron Fermi sea the correlation effects may manifest themselves in reactions on both neutral and charged currents. There are different sources for neutrinos of such energies, e.g., reactor neutrinos are good candidates. The

Sun and supernova neutrinos also have pronounced low energy tails. The observation of supernova neutrinos might provide us with unique information on the core-collapse and on the compact star formation and cooling [16]. Geo-neutrinos and antineutrinos from the progenies of U, Th and \(^{40}\)K decays inside the Earth bring to the surface information from the whole planet, about its content of radioactive elements [45]. Finally, verifying the existence of the relic neutrino sea with temperature \( T_\nu/T_\gamma = (4/11)^{1/3} \) represents one of the main challenges of the modern cosmology [15].

From a general point of view, our results strongly support the conclusion of Refs. [2, 4, 11, 12] about the essential role played by different medium effects in the neutrino evolution of neutron stars, as it was demonstrated in the framework of the "nuclear-medium cooling scenario" [13, 14, 23]. Without a proper inclusion of medium effects it is difficult to reach sound conclusions. Further investigations in this direction are required.

**APPENDIX A: CALCULATION WITH BARE VERTICES IN THE LOOP**

Let us now comment on results of previous calculations of the neutron PBF emissivity. If, as in calculations [16, 22], one neglects contributions from the anomalous vertices \( \bar{\tau} \), i.e. \( M \rightarrow 0 \) and \( L \rightarrow L \) in \( \langle A \rangle \), and puts \( \gamma_\alpha = 1 \), one may recover results of calculations with bare vertices ("b.v."). Expression (29) for \( \kappa^b_{\nu} \) becomes

\[
\kappa^b_{\nu} = \tilde{3} \left[ \tilde{q}^2 (L(n, q; +1))_n \\
+ \tilde{v}_F^2 (\omega^2 + (\tilde{q}^2)^2 - \tilde{q}^2) L(n, q; -1))_n \\
- \omega ((\tilde{q}^2)(L(n, q; +1) + L(n, q; -1))_n \right]. (A1)
\]

In the axial-vector channel the corresponding quantity is \( \kappa^b_{A} \propto v_F^2 \). Therefore we will keep also the \( v_F^2 \) corrections in (A1). In calculations [16, 22] such terms were dropped. The second term in (A1) can be indeed neglected, as being \( \sim v_F^2 \), since \( (L(n, q; -1))_n \propto v_F^2 \). The third crossing term of the order \( v_F^2 \) disordered in previous calculations can be dropped only, if conditions (20) hold, that is not the case for the bare vector current-current correlator. We keep this term here. For \( |q| v_F \ll \omega \) (i.e. for \( v_F \ll 1 \)}
since $|\vec{q}| \lesssim \omega$ we get

$$\frac{\eta_{b,v}^{a\omega}}{\rho^2} \approx -q^2 \mathcal{G} \left( \frac{\omega^2 - (\vec{v} \cdot \vec{q})^2}{4 \Delta^2} \right) - \frac{q^4}{27} v_F^2 \mathcal{G} \left( \frac{\omega^2}{4 \Delta^2} \right)$$

$$+ \frac{2}{3} q^2 v_F^2 \mathcal{G} \left( \frac{\omega^2}{4 \Delta^2} \right).$$

(A2)

The first line in (A2) comes from the expansion of the first term in (A1). The first term in the second line follows from the crossing term in (A1). Using (A2) we calculate

$$Q_{b,v} = \left( 1 + \frac{5}{21} v_F^2 - \frac{2}{3} v_F^2 \right) Q^{(0)}(\omega).$$

Dropping the $v_F^2$ corrections and using expression (27) for $Q^{(0)}$ one may reproduce the vector current contribution to the emissivity obtained in Refs. 16, 22 (and 2, 17), provided one sets there $\gamma_V = 0$).

The expression for the emissivity of neutron PBF on the axial-vector current calculated with the bare vertices in the loop does not deviate from that in (35) derived above with the full vertices. Note, however, that second and third terms in (35) differ from those used in previous calculations.
