Background: PAP-III is a secretory protein expressed in injured nerves. Results: Extracellular PAP-III formed fibrillar structures upon proteolytic N-terminal processing, interacted with neuronal surfaces, and enhanced neurite extension. Conclusion: Fibrillar PAP-III formed around injury sites may serve as a scaffold for the growth of regenerating axons. Significance: Clarifying fibrillar PAP-III functions would provide a novel strategy for nerve regeneration.

Pancreatitis-associated protein (PAP)-III, also known as regenerating gene/regenerating islet-derived (Reg)-III, is a small secretory protein whose expression is substantially induced in injured nerves. Here, we found that PAP-III protein underwent proteolytic N-terminal processing by trypsin-like protease(s) in injured sciatic nerves after axotomy. In vitro studies demonstrated that the N terminus-truncated PAP-III (ΔN-PAP-III) polymerized into a filament with a relatively uniform diameter of 10–20 nm, and the filaments formed higher order structures in a Na⁺ concentration-dependent manner. When the ΔN-PAP-III fibers were added to the culture media, the ΔN-PAP-III fibers were tightly attached to neurites and somata of primary cortical neurons in vitro. In contrast, little association with glial cells was observed. When dense matrices of ΔN-PAP-III fibers were sheeted on a culture dish, neurites preferentially adhered to the fibers, and neurite extension was enhanced. This neurite outgrowth activity was significantly suppressed by preincubation with antibodies against PAP-III. These results imply that the released PAP-III might be cleaved and forms ΔN-PAP-III fibers at the nerve injury sites. Consequently, these resulting fibers would provide regenerating axons with a platform for extension.

Pancreatitis-associated protein (PAP)² family members are small secretory proteins structurally classified as the calcium-dependent type (C-type) lectin. PAP-I was initially identified as a secretory molecule in the pancreas of rats with acute pancreatitis (1), and thereafter PAP-II and -III were cloned by the screening of cDNA libraries (2, 3). Because several family members have been identified in various animal species, the nomenclature of these molecules remains complicated (4, 5). The PAP family in rats consists of orthologs of the type III subclass of regenerating gene/regenerating islet-derived (Reg) family in mice; PAP-I (also called Reg-2) corresponds to Reg-IIIβ, PAP-II to Reg-IIIα, and PAP-III to Reg-IIIγ. PAP-III family members have been shown to play roles in the digestive system; for instance, PAP-I expression is enhanced by inflammation in intestine as well as in pancreas and acts as an anti-inflammatory molecule (6–8). PAP-III, whose expression is induced by an interaction of epithelial cells with bacteria in the gut, controls the innate immune system by killing bacteria (9–12).

In addition to the digestive system, several studies have revealed pivotal roles of PAP molecules in neuronal regeneration. Although the basal expression of PAP family members is almost nonexistent in the adult nervous system, they are markedly induced following neural injury. The expression of PAP-I is specifically induced in injured neurons both in the central nervous system and the peripheral nervous system (4, 13–18). It has been suggested that secreted PAP-I promotes neuronal regeneration by acting as a neuronal autocrine/paracrine survival factor as well as a mitogen for Schwann cells (13, 15, 18–20). In contrast to PAP-I, functional consequences of PAP-III expression have been less studied. The expression of PAP-III is also induced in injured neurons after central nervous system injury (16, 17). Unlike PAP-I, the induction of PAP-III expression does not occur in injured neurons in the peripheral nervous system; however, prominent expression has been observed in injured nerves in which Schwann cells serve as the putative sources of PAP-III (4). Our study further reveals that PAP-III secreted around injured peripheral nerves acts as a potent chemottractor for macrophages, which is required for the removal of...
myelin and axonal debris in injured nerves (21–23). PAP-III overexpression by adenoviral injection into injured sciatic nerves not only promoted macrophage infiltration into injured nerve but also enhanced axonal regeneration in rats (23). Although these results demonstrated a crucial role of PAP-III in nerve regeneration, it is possible that PAP-III may possess additional functions. In this study we addressed this possibility and found that PAP-III formed fibrillar structures upon N-terminal proteolytic processing and associated specifically with neurons to promote neurite extension.

EXPERIMENTAL PROCEDURES

Animals and Surgery—All experimental procedures were conducted in accordance with the standard guidelines for animal experiments of the Osaka City University and Nagoya University Graduate Schools of Medicine. Adult male Wistar rats, weighing about 150 g (SLC, Hamamatsu, Japan), were anesthetized with pentobarbital (40 mg/kg), and their sciatic nerves were transected with scissors. Control nerves and distal segments of injured nerves 1, 3, and 7 days after surgery were harvested for RT-PCR and Western blot analyses.

RT-PCR—Total RNA was obtained by the acid guanidine isothiocyanate/phenol/chloroform extraction method. cDNA was converted from total RNA with SuperScript III (Invitrogen) and used for PCR amplification. Amplification was carried out in 23 cycles for GAPDH or 32 cycles for PAP-III at 94 °C for 30 s, at 60 °C for 30 s, and at 72 °C for 30 s using primers described in our previous paper (4). The amplified products were loaded onto a 1.2% agarose gel and stained with ethidium bromide.

Western Blotting—Sciatic nerves and ilea were lysed in a buffer containing 8 M urea and 2% CHAPS as described previously (24). The supernatants (16–22 μg) were loaded onto 5–20% gradient gels (Wako Chemicals, Osaka, Japan) together with 10 ng of recombinant PAP-III protein treated with or without trypsin as described below. Blots were prepared on polyvinylidene difluoride membranes (Millipore). The membrane was probed with a mouse monoclonal anti-GAPDH antibody (Ambion, Huntington, UK) or a rabbit polyclonal anti-PAP-III antibody produced in our previous study and then with horseradish peroxidase-conjugated secondary antibodies (GE Healthcare) (4). Images were visualized by chemiluminescence (ECL Prime; GE Healthcare).

Precipitability of N Terminus-truncated PAP-III (ΔN-PAP-III) Processed by Trypsin—Recombinant PAP-III protein was purified from Pichia pastoris transformed with a rat PAP-III expression vector (4, 25). One microgram of PAP-III protein was treated with 0.1 μg of trypsin in a 20-μl solution of 25 mM Tris (pH 7.5) containing 0, 25, or 150 mM NaCl for 2, 5, or 12 h at room temperature. Then the reaction mixtures were centrifuged at 20,000 × g for 20 min at 4 °C, and supernatants and pellets were dissolved in 2 × and 1 × Laemmli sample buffer, respectively. After boiling, both samples were subjected to 15% SDS-PAGE, and proteins were visualized by staining with Coomassie Brilliant Blue R-250.

Microscopic Observation of ΔN-PAP-III Structure—PAP-III protein (2.5 μg) was treated with or without 0.25 μg of trypsin in a 25-μl solution of 25 mM Tris (pH 7.5) containing 0, 25, or 150 mM NaCl. For the control experiment, an equivalent amount (77 ng) of synthesized N-terminal 11 amino acids (EDAKEDVPTSR37) of PAP-III (PAP-III (N)) was diluted in a 25-μl solution of 25 mM Tris (pH 7.5) containing 150 mM NaCl. To examine the Ca2+ effect on the fiber shape, 25 mM Tris (pH 7.5), 150 mM NaCl solutions containing 2 mM EGTA or CaCl2 were used. The solutions were then diluted in 250 μl of the same buffers and incubated for 3 h at room temperature with poly-d-lysine (PDL)-coated 12-mm round glass coverslips placed on the bottom of 24-well culture dishes. We consistently used PDL in the present study because PDL cannot be hydrolyzed by trypsin (26). After a brief wash, proteins were fixed with 4% paraformaldehyde and then stained by a polyclonal anti-PAP-III antibody and anti-rabbit IgG conjugated with Alexa Fluor 488 (Invitrogen) for fluorescence observation. Images were acquired by confocal microscopes (TCS-SP5, Leica, Heidelberg, Germany; FV10i, Olympus, Tokyo, Japan). For scanning electron microscopy analyses, ΔN-PAP-III prepared on the coverslips was fixed with 2.5% glutaraldehyde and subsequently with 1% OsO4 in 0.1 M phosphate buffer. After dehydration with an ascending series of ethanol, the samples were immersed in isoamyl acetate and dried with a critical point dryer. Then the surfaces of the samples were coated with platinum using a sputter coater (E-1030; Hitachi, Tokyo, Japan). Images were acquired by S-4700 (Hitachi).

Generation of Monoclonal Anti-PAP-III Antibody—Rat monoclonal antibody was raised in accordance with the previous reports (27, 28). Briefly, a 10-week-old female WKY rat (SLC) was immunized with 100 μg of ΔN-PAP-III protein. Three weeks after immunization, lymph nodes obtained from the rat were dispersed, and lymphocytes were fused with mouse myeloma Sp2/0-Ag14 cells. The supernatants of hybridoma clones were screened by ELISA and subsequent immunostaining of ΔN-PAP-III fibers. A hybridoma clone was chosen, and the culture supernatant was loaded onto Hi-Trap SP column (GE Healthcare) to purify the antibody.

Cortical Cultures—Cortical neurons were prepared from cerebra of embryonic day (E) 18 embryonic Wistar rats as described previously (29). Neurons were seeded on PDL-coated 12-mm round glass coverslips placed on the bottom of 24-well culture dishes (1.5 × 105 cells/well) and precultured in Neurobasal medium (Invitrogen) containing 0.05 mg/ml penicillin/streptomycin (Invitrogen), 0.5 mM glutamine, and B27 supplement (Invitrogen) for 12–18 h or 10 days for the interaction assay. Astrocytes were also prepared from E18 Wistar rats (30) and maintained in DMEM containing 10% FBS and 0.05 mg/ml penicillin/streptomycin (hereafter referred to as DMEM/FBS). Microglia were isolated from a mixed culture of brains of neonatal Wistar rats on day 14–21 (31). Schwann cells were prepared from sciatic nerves of neonatal Wistar rats (32) and maintained in DMEM/FBS containing 10 μM forskolin (Calbiochem). Before the interaction assay, astrocytes, microglia, and Schwann cells were seeded on PDL-coated glass coverslips placed on the bottom of 24-well culture dishes and pre-cultured in DMEM/FBS for 12–18 h.

Interaction of ΔN-PAP-III Fibers with Primary Cultured Cells—PAP-III protein (2.5 μg) was treated with or without 0.25 μg of trypsin in a 25-μl solution of 25 mM Tris (pH 7.5) containing 150 mM NaCl for 2 h at room temperature, and the reaction was
stopped by the addition of 2.5 μg of trypsin inhibitor (Sigma). For the control experiment, an equivalent amount (77 ng) of PAP-III (N) was used. The reaction mixtures were added to culture media of each culture, and then cells were incubated for 24 h at 37 °C. After a brief wash with phosphate-buffered saline (PBS), samples were fixed with 4% paraformaldehyde and subjected to immunocytochemistry using polyclonal anti-PAP-III and mouse monoclonal anti-α-tubulin antibodies (Sigma) (24). Alexa Fluor 488- or 594-conjugated secondary antibodies (Invitrogen) and Alexa Fluor 594-conjugated phalloidin (Invitrogen) were used for visualization. Images were acquired by confocal microscopes (TCS-SP5 and FV10i). To examine the inhibition of interactions by anti-PAP-III antibodies, ΔN-PAP-III fibers were incubated with 2.5 μg of a normal rabbit IgG (R&D Systems), normal rat IgG (Sigma), polyclonal or monoclonal anti-PAP-III antibody for 2 h at room temperature before addition to the culture media.

Neurite Extension on ΔN-PAP-III Fibers—Trypsin digestion of PAP-III was performed on the top of coverslips to prepare dense fiber matrices of ΔN-PAP-III. PAP-III protein (1.0 μg) was diluted in a 10-μl solution of 25 mM Tris (pH 7.5) without NaCl. Immediately after the addition of 0.1 μg of trypsin, the solution was put on the center of PDL-coated 12-mm round glass coverslips placed on the bottom of 24-well culture dishes and incubated for 2 h at 37 °C. Coverslips were washed briefly with PBS, incubated for 30 min with 250 μl of PBS containing 1.0 μg of trypsin inhibitor, and then washed several times again. To examine antibody neutralization, coverslips were incubated with 250 μl of PBS containing anti-rabbit IgG (1.6 μg), polyclonal (1.6 μg), or monoclonal anti-PAP-III antibody (0.8 μg) for 2 h at room temperature. After brief washes, cortical neurons were seeded at a density of 1.5 × 10^5 or 5.0 × 10^5 cells/well. Neurons were maintained in Neurobasal medium containing 0.05 mg/ml penicillin/streptomycin, 0.5 mM glutamine, and B27 supplement (Invitrogen) for 36 h, fixed with 4% paraformaldehyde, and subjected to immunocytochemistry using polyclonal anti-PAP-III and anti-α-tubulin antibodies.

Effects of Full-length PAP-III and N-terminal Peptide on Neurite Extension—Cortical neurons were seeded at a density of 5.0 × 10^3 cells/well on PDL-coated 12-mm round glass coverslips placed on the bottom of 24-well culture dishes in the culture media described above. Full-length PAP-III (2.5 μg) and the equivalent amount (77 ng) of PAP-III (N) were added to the culture media immediately after seeding. Cells were cultures for 36 h, fixed with 4% paraformaldehyde, and stained by anti-α-tubulin antibody.

Quantification of Neurite Length—Cortical neurons cultured at a density of 5.0 × 10^3 cells/well were prepared as described above. Low magnification images were acquired randomly using a fluorescent microscope BX41 (Olympus), and neurites of individual neurons were measured using the Neuron J plug-in in the ImageJ software (National Institutes of Health, Bethesda, MD). At least 88 neurons from three independent cultures were analyzed.

RESULTS

Proteolytic N-terminal Processing of PAP-III after Injury—We first examined the expression of PAP-III in injured sciatic nerves. PAP-III mRNA was substantially induced in the injured nerves in 1 day, and the expression gradually decreased (Fig. 1A). Western blotting using PAP-III antibody demonstrated a similar pattern of expressions of PAP-III protein (Fig. 1B). We detected a ~14-kDa band in the injured nerves throughout the period, whereas the molecular mass of full-length protein was ~16-kDa. Tryptsin-like proteases were reported to act on PAP-III and remove the N-terminal 11 amino acids to generate a stable ~14-kDa product (25, 33). Although Na+ free conditions, solubility/pre-
Neurite Outgrowth by Fibrillar PAP-III

FIGURE 2. Precipitability of ΔN-PAP-III depends on Na$^+$ concentrations. A, PAP-III protein was incubated with (+) or without (−) trypsin in 25 mM Tris (pH 7.5) containing 0 (−), 25, and 150 mM NaCl for 2 h (hrs). B, PAP-III protein was treated with trypsin (+) in 25 mM Tris (pH 7.5) containing 150 mM NaCl for 2, 5, and 12 h. Solutions were centrifuged at 20,000 × g, and proteins in supernatant (S) and pellet (P) fractions were resolved by SDS-PAGE followed by Coomassie Brilliant Blue staining. ΔN-PAP-III is precipitated under 0 and 25 mM but not under 150 mM NaCl after 2 h of incubation. ΔN-PAP-III becomes precipitated even in the presence of 150 mM NaCl after 5 h of incubation.

was prolonged up to 12 h under 150 mM NaCl, the precipitation of ΔN-PAP-III was increased and could not be detected in the supernatant (Fig. 2B). These results imply that ΔN-PAP-III gradually loses solubility, and the speed of this precipitation was dependent on the salt concentration.

We next determined overall shapes of the insoluble ΔN-PAP-III by immunofluorescence and found apparent differences among different Na$^+$ concentrations (Fig. 3A). The ΔN-PAP-III formed a sheet-like structure in a neutral buffer without NaCl; however, it formed fibrils under 150 mM NaCl. Intermediate NaCl concentrations resulted in intermediate structures. Signals could not be detected in case of full-length protein or N-terminal 11 amino acids of PAP-III (PAP-III (N)) (Fig. 3B), indicating that ΔN-PAP-III was the component of these structures. PAP-III is structurally classified as C-type lectin; however, Ca$^{2+}$ did not affect the shapes (data not shown). To further characterize these insoluble structures, EM analyses were performed (Fig. 3C). Scanning electron microscopy demonstrated that a filament with a diameter of 10–20 nm was the minimal constituent in common. The sheet-like (meshwork) structure, under the NaCl-free condition, consisted of matrices of filaments branched and entangled tightly (Fig. 3C, a–c). In contrast, the filaments formed thicker bundles in the presence of 150 mM NaCl (Fig. 3C, d–f). These results indicate that the conformation patterns by ΔN-PAP-III filaments depend on environmental salt conditions, although ΔN-PAP-III polymerizes into a primary filament with a consistent diameter. We prepared either the fibrils or the meshwork matrices for the following assays.

Association of ΔN-PAP-III Fibers with Neuronal Surfaces—To address functions of extracellular ΔN-PAP-III fibers in the injured nervous system, we prepared primary cultures, added ΔN-PAP-III fibers to the culture media, and observed interactions of ΔN-PAP-III fibers with the cultured cells. The fibrillar ΔN-PAP-III produced in the presence of 150 mM NaCl was used for this experiment to observe the interactions in detail. Significant interactions with glial cells were not observed (Fig. 4). Exogenously added ΔN-PAP-III fibers adhered to the cell-free area of coverslips as well as on glial cells, although there were moderate tendencies for the ΔN-PAP-III fibers to attach preferentially to cellular surfaces. In contrast, significant interaction with neurons was observed (Fig. 5). When we added ΔN-PAP-III fibers to cultured cortical neurons, which were cultured for 12–18 h after seeding, ΔN-PAP-III fibers associated predominantly with growing neurites as well as neuronal somata (Fig. 5A). These associations were entirely blocked by preincubation of ΔN-PAP-III fibers with the rabbit polyclonal anti-PAP-III antibody before adding to the culture media (Fig. 5B). Moreover, the inhibition was confirmed by the use of rat monoclonal antibody, which we produced using ΔN-PAP-III fibers as an antigen. Control rabbit or rat IgG had no effect on the interactions (Fig. 5B and data not shown). In line with Fig. 3B, neither full-length PAP-III nor PAP-III (N) exhibited any signals on neuronal surfaces (data not shown). Such tight associations were also observed using matured cortical neurons, which were precultured for 10 days (data not shown).

Neurite Outgrowth Activity of ΔN-PAP-III Fibers—As shown by asterisks in Fig. 5A, a large complex of the accumulated fibrils was often observed on neuronal somata. Precise observations of these regions by confocal microscopy revealed that some neurites grew upward into the accumulated fibrillar complex.
Neurite Outgrowth by Fibrillar PAP-III

FIGURE 4. Weak interactions of exogenously added ΔN-PAP-III fibers with glial cells. ΔN-PAP-III fibers produced in 25 mM Tris (pH 7.5) containing 150 mM NaCl were added to the culture media of astrocytes, microglia, and Schwann cells, and incubated for 24 h. After fixation, ΔN-PAP-III fibers and cellular shapes were visualized by anti-PAP-III antibody (green) and phalloidin (red) staining, respectively. Scale bar, 50 μm.

FIGURE 5. Association of exogenously added ΔN-PAP-III fibers with neurons. ΔN-PAP-III fibers produced in 25 mM Tris (pH 7.5) containing 150 mM NaCl were added to the culture media of primary cortical neurons precultured for 12–18 h. Twenty-four hours after incubation, the preparations were fixed and immunostained with anti-PAP-III (green) and anti-α-tubulin (red) antibodies. A, ΔN-PAP-III fibers associated with neurites (arrows) as well as somata. Complexes of accumulated fibrils were often formed and accumulated on somata (asterisks), B, the associations were blocked by preincubating ΔN-PAP-III fibers with rabbit polyclonal (+ rab. pAb) or rat monoclonal anti-PAP-III (+ rat mAb) antibody, but not with normal rabbit IgG (+ normal rab. IgG). C, high magnification Z-stack images of regions where large complexes of ΔN-PAP-III fibers accumulates on somata (indicated by asterisks in A). Superficial images of the coverslips show a clear association of ΔN-PAP-III fibers with neurites (a–c, arrows). The top images show the upward growth of some neurites into accumulated fibrillar complex (d–f and g–i, arrowheads). Maximum projections of XY (j–l) and YZ (m–o) planes. Neurites grow upward only in the presence of fibrillar complexes (m–o). Scale bars, 50 μm (A and B) and 10 μm (C).

DISCUSSION

In this study we have demonstrated that the nerve injury-induced secretory protein PAP-III is cleaved and subsequently forms 10–20 nm filamentous structures. In vitro, the filaments provide neurites with a scaffold to facilitate neurite elongation. Previously, we demonstrated that PAP-III expression was sub-
stantially induced in injured peripheral nerves (4, 23). Although in those studies we did not address the cleavage form of PAP-III, we found, in the present study, a 14-kDa product of PAP-III in injured nerves throughout the period we examined (Fig. 1B). It is unlikely that this smaller product is derived from a splicing variant because no mRNA variants have been identified in our present and previous studies and in the NCBI database. A previous study showed that intestinal Reg-III, the mouse ortholog of PAP-III, actually underwent processing by trypsin-like protease(s) at the C terminus of conserved Arg37 in vivo (34). This cleavage site was identical to that where trypsin recognized the recombinant protein in vitro, and the N-terminal processing at this site could be essential for the bactericidal activity as well as conformation of the protein. Although the cleavage site of PAP-III remained uncertain in injured nerves, the size of the product was almost equal to the intestinal one (Fig. 1C), and it is likely that PAP-III is also cleaved at the C terminus of Arg37 in vivo. Processing enzyme(s) for PAP-III remain to be identified in vivo. Along with the context of the previous report in the intestine (34), we assume that PAP-III might be cleaved in the extracellular milieu immediately after secretion. An identification of potent protease(s) could be important for understanding how PAP-III activity is regulated by the nerve injury.

PAP family members and their orthologs are commonly cleaved at the C terminus of Arg37 (5, 25, 33–35). In addition to PAP-III, rat PAP-I and its putative human ortholog hepatocarcinoma-intestine-pancreas (HIP)/PAP were shown to become insoluble after the N-terminal processing at neutral pH (25, 33, 35). However, those studies were carried out in the absence of Na+, which was a nonphysiological condition. We therefore examined the correlation between Na+ concentration and the precipitability of PAP-III, and we demonstrated that the precipitability and the precipitated fibrillar structures varied depending on the Na+ concentrations. The precipitability and precipitation speed of PAP-III became lower and slower, respectively, as Na+ concentration increased (Fig. 2). However the present study demonstrated that the precipitation and the formation of filamentous structure could occur even under physiological conditions (Figs. 2 and 3). The present confocal and subsequent EM studies demonstrated that the precipitation, which was a polymerized PAP-III, was composed of

FIGURE 6. Neurite extension on ΔN-PAP-III fibers immobilized on glass coverslips. Dense matrices of ΔN-PAP-III fibers were prepared on PDL-coated glass coverslips by digesting ΔN-PAP-III without NaCl. Primary cortical neurons were seeded on them and cultured for 36 h. Neuronal shapes were defined by immunostaining with anti-α-tubulin antibody (red). A, image of regions where bundles of ΔN-PAP-III fibers were sparsely formed (green). Neurites (arrows) as well as somata adhere predominantly to the thick fibrils. Scale bar, 100 μm. B, representative images of neurons extending neurites on PDL (control), PDL + ΔN-PAP-III fibers (ΔN-PAP-III fibers) in the presence of rabbit polyclonal (ΔN-PAP-III fibers + pAb) or rat monoclonal (ΔN-PAP-III fibers + mAb) antibody. relatively uniform primary filament (10–20 nm in diameter) in
the presence or absence of Na+/H11001 (Fig. 3). However, the confor-
mational patterns by the primary filaments were different
depending on the concentration of Na+/H11001. In the presence of 150
mM NaCl, several filaments made a thicker bundle. In contrast,
in lower concentrations of Na+/H11001 the bundles composed of the
primary filaments showed branched and entangled structures
and eventually formed a meshwork, which was in accordance
with the observation in a previous paper (25). Some members of
the PAP family were biochemically shown to form oligomers
(36, 37), and furthermore the degree of oligomerization of
human HIP/PAP was shown to be dependent on Na+ concentra-
tion (38). The oligomerization state of the protein before
processing may have an influence on the conformation such as
bundling, branching, and meshwork composed of ΔN/PAP-III
filaments.

To address significances of the fibrillar structure, we pre-
pared dense mesh-like matrices of ΔN-PAP-III on coverslips
and demonstrated that the neurites were preferentially adhered
to and elongate along the fibrillar ΔN-PAP-III (Fig. 6). Neurite
elongation was significantly promoted on dense matrices of
ΔN-PAP-III, and the neurite elongation activity of the fibrillar
ΔN-PAP-III was decreased to almost control levels by preincu-
bation of the matrices with antibodies against PAP-III (Fig. 6,
B–D). Recently, it was reported that full-length Reg-I, which
belong to a distant family of PAP/Reg-III, stimulated neurite
outgrowth (39). This was not the case with PAP-III. Neuronal
morphologies were unchanged when the full-length protein
was added to the culture media of cortical neurons (Fig. 7). In
addition, the N-terminal peptide cleaved by trypsin, PAP-III
(N), did not alter neurite length (Fig. 7). These results indicate
that the cleaved N-terminal fragment and the full-length PAP-
III, which are soluble, do not function as a neurite elongation
factor and suggest that the N-terminal truncation of PAP-III or
composition of the fibrillar structure would be necessary for
promoting neurite outgrowth.

One of the intriguing findings in this study is that the associ-
ation of the fibrillar ΔN-PAP-III is neuronal cell-specific (Fig.
5). Specific interactions between the fibrillar ΔN-PAP-III and
glial cells or various nonneuronal cell lines were not observed
(Fig. 4 and data not shown), suggesting that there may exist
neuronal surface-specific molecule(s) having an affinity with
ΔN-PAP-III. PAP family members are reported to bind to cer-
tain carbohydrates such as mannan, chitin, and bacterial pepti-
doglycan as a lectin (9, 35, 40). Thus, it is likely that ΔN-PAP-III
recognizes and binds to sugar chains of membrane-bound pro-
teins or lipids, which are preferentially expressed on neurons.
Alternatively, it is also possible that ΔN-PAP-III may directly
bind to the neuronal membrane via receptor-like molecules.
Fibrillar proteins such as collagen and fibronectin promote
neurite outgrowth by binding to their receptors, such as a com-
bination of integrin heterodimers expressed on neuronal sur-
faces (41, 42). Further studies are needed to investigate molec-

FIGURE 7. No significant effects of exogenously added full-length PAP-III or PAP-III (N) on neurite extension. Primary cortical neurons were seeded on
PDL-coated glass coverslips and cultured for 36 h in media containing no PAP-III (control), full-length PAP-III, or PAP-III (N). Neuronal shapes were defined by
immunostaining with anti-α-tubulin antibody (red). A, representative images of neurons. Scale bar, 100 μm. B, quantification of the total neurite length. C,

Neurite Outgrowth by Fibrillar PAP-III

ular mechanisms underlying the neuron-specific adhesion and the neurite outgrowth activity of the fibrous ΔN-PAP-III.

In this study we demonstrated the neurite elongation activity of ΔN-PAP-III using the cortical neurons. This suggests that neurites of cortical neurons are capable of binding to ΔN-PAP-III and the adhesion could promote the neurite elongation. Indeed a traumatic injury of the cortex also demonstrated an induction of PAP-III expression (16). However, in the case of central nervous system injury, most neurons are highly susceptible to injury and eventually die without elongating neurites. In this respect, when injured neurons are successfully protected by some treatments, the ΔN-PAP-III may be advantageous for the protected neurons to promote their neurite elongation. Regarding the actual structure of ΔN-PAP-III in vivo, we were not able to identify the fibrillar structure in the nerve injury site. Although our antibody clearly visualized PAP-III proteins in other brain lesion models (16, 17), immunohistochemical analyses did not show convincing results in injured nerve. One possibility may be that PAP-III conformation is suggested that the antibacterial activity of mouse Reg-III proteins in injured nerves may also switch the PAP gene family.

Acknowledgments—We thank Dr. S. Kawahara, I. Noura, C. Kadono, and Y. Tabata for technical assistance and A. Asano for secretarial assistance. Chemiluminescence, scanning electron and confocal microscopy were performed at the Central Laboratory of Osaka City University Medical School.
