Aromatase inhibition in the treatment of advanced breast cancer: is there a relationship between potency and clinical efficacy?

R Sainsbury*,1

Two-thirds of breast tumours are oestrogen-receptor positive and 60–70% of these tumours respond to interventions that reduce the effects of oestrogen. Until recently, tamoxifen was the drug of choice for the treatment of hormone-responsive early and advanced breast cancer. However, tamoxifen is associated with increased incidences of endometrial cancer and thromboembolic disease, and many tumours eventually become resistant to treatment with tamoxifen. Thus, there is a need for alternative therapies with different mechanisms of action. In postmenopausal women, aromatase inhibitors (AIs) suppress oestrogen levels by inhibiting oestrogen synthesis via the aromatase enzyme pathway. The third-generation AIs (anastrozole, letrozole and exemestane) are more potent than the earlier AIs (aminoglutethimide, formestane and fadrozole) with respect to both aromatase inhibition and oestrogen suppression. While the earlier AIs were unable to show any benefit over megestrol acetate or tamoxifen as second- and first-line therapy, respectively, in postmenopausal women with advanced breast cancer, third-generation AIs have shown significant benefits in both settings. Comparison of aromatase inhibition and oestrogen suppression between the third-generation AIs anastrozole and letrozole showed a small but significantly greater difference in the degree of suppression of oestrone and oestrone sulphate (but not oestradiol), with letrozole. In an open-label trial, there were no significant differences between letrozole and anastrozole for the clinical end points of time to progression (primary end point), time to treatment failure, overall survival, clinical benefit, duration of clinical benefit, time to response, duration of response or objective response rate in patients with confirmed hormone receptor-positive tumours. Together these data suggest that once a certain threshold of aromatase inhibition is reached, small differences in oestrogen suppression between the third-generation AIs do not lead to clinically significant differences in overall efficacy.

Keywords: anastrozole; aromatase inhibition; oestrogen suppression; potency; clinical efficacy

Breast cancer is regarded world wide as a major cause of morbidity and mortality in both pre- and postmenopausal women, and currently comprises 18% of all female cancers (McPherson et al, 2000). In the UK, breast cancer accounts for more than 14 000 deaths each year (McPherson et al, 2000), while in Europe in 1995 it was responsible for the deaths of 124 000 women (Bray et al, 2002). However, between 1988 and 1998 mortality from the disease fell dramatically among women below the age of 70 years in Western (but not Eastern) Europe (Levi et al, 2001). Possible reasons for this improved mortality rate include the introduction of national breast screening programmes and new better treatment regimens (Blanks et al, 2000; Levi et al, 2001).

It is recognised that two-thirds of breast tumours are oestrogen-receptor positive and women who have hormone receptor-positive tumours are suitable candidates for endocrine therapy (Forbes, 1997). The use of endocrine therapy for the management of the disease has grown dramatically since the first pioneering report by Beatson in 1896 of a successful outcome in a premenopausal woman with breast cancer following ovarian ablation (Beatson, 1896), and many different treatment approaches are now available. Although significant progress has been made over the past three decades in terms of both improved efficacy and tolerability of endocrine treatments for breast cancer, many challenges still lie ahead for both surgeons and oncologists in the treatment and management of all stages of the disease.

Until recently, and for more than 30 years, tamoxifen – a selective oestrogen receptor modulator (SERM) – had been the drug of choice for the treatment of hormone-responsive early and advanced breast cancer. However, although tamoxifen is an effective treatment, it has partial agonist activity. This is associated with an increase in the incidence of endometrial cancer (Fisher et al, 1996) and of thromboembolic disease (Jaiyesimi et al, 1995; Fisher et al, 1996), and limits its use. In addition, most tumours eventually become resistant to tamoxifen and alternative treatments are required. In recent years, a number of different classes of endocrine therapy have emerged as suitable alternatives in the treatment of advanced breast disease. Although several new SERMs have been developed (e.g. raloxifene), they have not been shown to produce any clinically relevant effects in the treatment of tamoxifen-resistant tumours (Johnston, 2001). Thus, there is a need for new therapies with improved tolerability profiles that are not cross-resistant with established endocrine therapies such as tamoxifen. The availability of endocrine agents with different
Mechanisms of action to tamoxifen, such as the aromatase inhibitors (AIs), is an important step forward in the search to provide more efficacious and better-tolerated therapies.

The AIs have been developed for the treatment of women with breast cancer in whom ovarian function has ceased either due to the menopause or as a result of ovarian ablation, through oophorectomy or by ovarian irradiation. They prevent the formation of oestrogen from androgens in postmenopausal women through inhibition of the cytochrome P450 enzyme, aromatase, which catalyses the conversion of androgens to oestrogens in the fat, liver and muscle cells (Dowsett et al., 1995; Geisler et al., 1996) and breast tumour tissue itself (Bhatnagar et al., 2001; Geisler et al., 2001). In premenopausal women, the ovaries are the primary site of oestrogen production and AIs are not able to completely block ovarian oestrogen synthesis.

Aminogluthimide was the first AI to become available in the late 1970s (Wells et al., 1978) and the first to show efficacy as second-line therapy after tamoxifen in postmenopausal women with advanced hormone-responsive breast cancer. However, its toxicity and lack of selectivity for the aromatase enzyme, necessitating concomitant corticosteroid supplementation (Wells et al., 1978), prevented it from becoming a more widely used treatment. Formestane, a steroidal AI, became available in 1993. It was also effective for treatment of postmenopausal women with advanced breast cancer, but more selective than aminogluthimide, and therefore associated with fewer side effects. However, as a result of extensive first-pass metabolism, formestane cannot be given orally and has to be administered twice-monthly by intramuscular injection, leading to reports of local reactions in up to 17% of patients (Goss et al., 1986).

The newer third-generation AIs, which include the nonsteroidal agents, anastrozole, letrozole and fadrozole (Japan only) and the steroidal compound, exemestane (Figure 1), are the most recent AIs to become available for use in postmenopausal women with metastatic hormone-responsive breast tumours. These AIs show increased potency with respect to both aromatase inhibition and oestrogen suppression compared with the earlier AIs. Small but statistically significant differences in potency have also been reported between third-generation AIs (Geisler et al., 2002).

An important question is whether or not these differences in potency between the third-generation AIs lead to clinically relevant differences in efficacy and tolerability. This paper reviews current published data on potency and clinical efficacy to determine if any such relationship exists.

### Whole-body Oestrogen Suppression and Aromatase Inhibition

**Comparison of first- and second- vs third-generation aromatase inhibitors: oestrogen suppression and aromatase inhibition**

Indirect comparisons of oestrogen suppression by the first- and second-generation AIs aminoglutethimide, formestane and fadrozole and the third-generation AIs anastrozole and exemestane that were conducted in the same laboratory, have shown that third-generation AIs are more potent than the earlier AIs (Figure 2). These studies demonstrated that aminogluthimide (1000 mg once daily (o.d.)) suppressed oestradiol levels by 75% (MacNeill et al., 1992), while formestane (250 mg o.d.) and fadrozole (1 mg twice daily) suppressed oestradiol by approximately 59% (Dowsett et al., 1990; Lonning et al., 1991; Jones et al., 1992). Anastrozole (1 mg o.d.) and exemestane (10 mg o.d.) showed similar activities to each other (84% vs 85%, respectively) and were more potent than aminogluthimide, formestane and fadrozole (Geisler et al., 1996; Johannessen et al., 1997). Similar differences between the agents were observed with respect to aromatase inhibition (Figure 2). An unrelated study comparing anastrozole (1 mg o.d.) with letrozole (2.5 mg o.d.) (Geisler et al., 2002) showed that anastrozole was as potent as letrozole in terms of oestradiol suppression (84.9% vs 87.8%, respectively, P = 0.1088), although the difference in aromatase inhibition between anastrozole and letrozole was significant (97.3% vs > 99.1%, respectively, P = 0.0022) (Figure 2) (Geisler et al., 2002).

**Direct comparison of third-generation aromatase inhibitors, anastrozole and letrozole: oestrogen suppression**

The study in which anastrozole was directly compared with letrozole (Geisler et al., 2002) was a small-scale, randomised, double-blind, cross-over trial. In all, 12 postmenopausal women with oestrogen receptor-positive metastatic tumours suitable for treatment with AIs were enroled into the study. Six patients received 6 weeks of anastrozole (1 mg o.d.) followed by 6 weeks of letrozole (2.5 mg o.d.), while the other six received 6 weeks of letrozole followed by 6 weeks of anastrozole. Compared with anastrozole, letrozole showed small but significantly increased suppression of oestrone and oestradiol sulphate concentrations (Figure 3), but as discussed above, there was no difference in suppression of oestradiol (Geisler et al., 2002).

### Clinical Efficacy

**Comparison of the third-generation aromatase inhibitors with megestrol acetate and aminogluthimide as second-line therapy for advanced breast cancer**

Several Phase III studies have compared the efficacy of the third-generation AIs in postmenopausal women with advanced breast cancer who have progressed on tamoxifen, vs the previous standard treatments in this setting, megestrol acetate or aminogluthimide (Table 1).

The efficacy of anastrozole (1 mg or 10 mg od) compared with megestrol acetate [40 mg four times daily (qd)] has been assessed in two trials, one European (Jonat et al., 1996) and one North American (Buzdar et al., 1997), prospectively planned for combined analysis (Buzdar et al., 1996a). The results summarized in Table 1 are of the combined analysis.

After a median follow-up of 6 months, time to progression (TTP) and objective response (OR = complete + partial response) rate did not differ significantly for the 1 and 10 mg anastrozole groups compared with the megestrol acetate group (Table 1). The
overall median TTP was approximately 21 weeks and approximately one-third of patients in each treatment group benefited from therapy (Buzdar et al, 1996a). After 31 months of follow-up (Buzdar et al, 1998), anastrozole (1 mg) demonstrated a significant survival advantage over megestrol acetate (Table 1). There was no significant difference for overall survival between anastrozole 10 mg and megestrol acetate, although numerical advantages have been shown in favour of anastrozole 10 mg, with longer median time to death (25.5 vs 22.5 months for anastrozole 10 mg and megestrol acetate, respectively; \( P = 0.09 \)) and lower death rate at 2 years (45.4 vs 53.7%, respectively). Therefore, while there was no advantage for the higher dose of anastrozole, the data are consistent with, and supportive, of the findings observed with the clinically approved 1 mg dose.

Two trials have investigated the efficacy of letrozole (2.5 or 0.5 mg o.d.) vs megestrol acetate 40 mg q.d. (Dombernowsky et al, 1998; Chaudri and Trunet, 1999; Buzdar et al, 2001) (Table 1). Results of the European trial (Dombernowsky et al, 1998) showed the OR rate was significantly higher for patients receiving letrozole 2.5 mg than for letrozole 0.5 mg \( (P = 0.004) \) or megestrol acetate \( (P = 0.04) \) (24, 13 and 16%, respectively). Letrozole 2.5 mg was superior to letrozole 0.5 mg for TTP \( (P = 0.02) \), but not compared with megestrol acetate. At a 51-month follow-up analysis for the letrozole 2.5 mg arm (Chaudri and Trunet, 1999), letrozole did not show significant survival benefit over megestrol acetate (Table 1). In the US trial (Buzdar et al, 2001), no significant differences were reported for TTP (Table 1) or OR rate and, contrary to the first trial, the efficacy of letrozole was not dose related. No significant survival benefit was seen for letrozole vs megestrol acetate (Table 1). It has been speculated that these contradictory findings may be the result of an imbalance of prognostic factors in favour of megestrol acetate in the latter trial (Wischnewsky et al, 2002).

In a further open-label trial, letrozole (2.5 and 0.5 mg o.d.) was compared with aminoglutethimide (250 mg, twice daily) (Gershnovich et al, 1998) (Table 1). The higher dose of letrozole (2.5 mg daily) was superior to aminoglutethimide for overall survival \( (P = 0.002) \), TTP (Cox regression analysis, \( P = 0.008 \)) and TTF (Cox regression analysis, \( P = 0.003 \)). There were no significant differences in OR seen in patients receiving letrozole 2.5 mg, letrozole 0.5 mg or aminoglutethimide. Letrozole 2.5 mg showed a significant advantage over the letrozole 0.5 mg dose for survival \( (P = 0.04) \), but there was not a significant dose–response effect for letrozole in terms of TTP, in line with the results from the US trial of letrozole vs megestrol acetate (Buzdar et al, 2001). In addition, a trial that assessed the impact of letrozole 2.5 and 0.5 mg o.d. on peripheral aromatisation of androstenedione to oestrone
Table 1  Overview of efficacy results from Phase III trials of second-line treatment of advanced breast cancer. A = anastrozole; L = letrozole; TTP = time to disease progression; NA = not available; HR+ve = hormone receptor-positive; CB = clinical benefit; OR = objective response; NS = not significant.

Overall, although there have been some differences in outcome and the end points at which significant benefits have been observed, the newer-generation AIs have all proven more effective and better tolerated than the progestogen megestrol acetate, and letrozole has demonstrated superior efficacy to aminoglutethimide, for the second-line treatment of patients with advanced breast cancer failing on tamoxifen. As a result, third-generation AIs are now established as the standard treatment in this patient population. In contrast, the second-generation AIs formestane and fadrozole have shown no significant efficacy benefits over megestrol acetate in patients progressing on tamoxifen (Buzdar et al, 1996b; Thürlimann et al, 1997).

Comparison of the third-generation aromatase inhibitors with tamoxifen as first-line therapy for advanced breast cancer

Results of the Phase III studies assessing the efficacy of the third-generation AIs vs tamoxifen as first-line therapy in postmenopau-
sal women with advanced breast cancer are summarised in Table 2. These data indicate the superiority of the third-generation nonsteroidal AIs compared with tamoxifen in this patient population.

The efficacy of anastrozole vs tamoxifen was assessed in two Phase III trials, one European (the Tamoxifen and Arimidex Randomized Group Efficacy and Tolerability (TARGET) trial) (Bonneterre et al, 2000) and one North American (Nabholtz et al, 2000), which were identical in design and prospectively planned for combined analysis. Anastrozole was shown to be at least as effective as tamoxifen as first-line treatment of postmenopausal women with advanced breast cancer, although some variation in data was observed between the two individual Phase III trials (depending upon the proportion of patients whose tumours were hormone receptor-positive). In the North American trial, TTP and clinical benefit (CB) rates were significantly better for anastrozole compared with tamoxifen (Table 2). In the TARGET trial, anastrozole was shown to be equivalent to tamoxifen in terms of TTP and OR rates (Table 2). The difference in outcome was attributed to differences in the proportion of patients with confirmed hormone receptor-positive tumours (89 vs 45% for the North American and TARGET trials, respectively). Analysis of the subgroup that comprised only patients with hormone receptor-positive tumours (45%) in the TARGET trial showed a similar separation of the Kaplan–Meier curves to that seen in the overall population in the North American trial (in which 89% of patients had hormone receptor-positive tumours). The combined analysis of the two trials also showed anastrozole to be superior to tamoxifen for TTP in patients with hormone-sensitive advanced breast cancer (Table 2) (Bonneterre et al, 2001).

In a single Phase III study in postmenopausal women with advanced breast cancer, letrozole was also found to be superior to tamoxifen for several efficacy end points (Mouridsen et al, 2001). Time to progression, CB and OR rates were significantly better for letrozole (Table 2). In addition, TTF was significantly longer for letrozole compared with tamoxifen (median TTF: 9.2 vs 5.7 months, respectively, P = 0.0001).

Although no data from Phase III trials of exemestane are currently available, the results of a Phase II trial of exemestane (25 mg o.d., n = 31) vs tamoxifen (20 mg o.d., n = 32) are promising (Pardiens et al, 2000). Median TTP was 8.9 vs 5.2 months in the exemestane and tamoxifen, respectively, and OR rates were 42 vs 16%, respectively. A Phase III trial is ongoing.

In contrast to the third-generation AIs, the second-generation agents fadrozole and formestane have not shown any significant efficacy benefits over tamoxifen in the advanced disease setting (Perez Carrion et al, 1994; Falkson and Falkson, 1996).

Direct comparison of the third-generation aromatase inhibitors: anastrozole vs letrozole as second-line therapy

Anastrozole (1 mg o.d.) and letrozole (2.5 mg o.d.) were compared as second-line treatment for advanced breast cancer with hormone receptor-positive or unknown receptor status in postmenopausal women who had progressed on tamoxifen in a multicentre, open-label, randomised Phase III–IV study (Rose et al, 2002). The primary end point was TTP and secondary end points included OR rate, response duration, duration of clinical benefit, TTF, time to response and overall survival (OS).

A total of 713 postmenopausal patients were randomly allocated to either letrozole 2.5 mg o.d. (n = 356) or anastrozole 1 mg o.d. (n = 357). Patient characteristics were well balanced between treatment groups (Rose et al, 2002). A total of 48% of patients had hormone receptor-positive tumours (Rose et al, 2002). Efficacy end points are shown in Table 3. In the overall population, anastrozole was similar to letrozole for TTP (P = 0.920), TTF (P = 0.761) and OS (P = 0.624). The only differences between anastrozole and letrozole were for OR rate in both the overall population and the unknown receptor status subgroup, which were higher in the letrozole vs the anastrozole group (overall population: 19.1 vs 12.3%, odds ratio = 1.70, P = 0.014; unknown receptor status subgroup: 20.8 vs 8.4%, respectively) (Rose et al, 2002). In fact, in patients with confirmed hormone receptor-positive tumours there was no difference in OR between anastrozole and letrozole (28/167 [16.8%] vs 30/173 [17.3%], respectively). As the overall population included patients with unknown receptor status, it is possible that in this unknown receptor group there was a greater number of patients randomised to letrozole who had hormone receptor-positive tumours and who would respond to letrozole. If this was the case, it could account for the higher OR rate with letrozole in the overall population. Presently, the number of patients with unknown receptor status in each group has not been published. Furthermore, no results for TTP in the hormone receptor-positive population have been published to date, so the relative efficacy of anastrozole and letrozole for this end point is uncertain.

SUMMARY

The AIs have been developed for treatment of breast cancer in postmenopausal women with hormone receptor-positive tumours and it is important that they are used to treat this group of patients. Third-generation AIs (anastrozole, letrozole and exemestane) show improved potency with respect to suppression of aromatase activity and circulating oestrogen levels compared with the older-generation AIs (aminogluthethimide, formestane and fadrozole) (Dowsett et al, 1990; Lonnning et al, 1991; Jones et al, 1992; MacNeill et al, 1992; Geisler et al, 1996). This increased potency correlates with improved clinical efficacy of the third-generation AIs relative to the older drugs. Thus, while formestane and fadrozole, which inhibit aromatase by < 85%, have shown no benefits over r–IUGA (Buzdar et al, 1996b; Thürlimann et al, 1997) or tamoxifen (Perez Carrion et al, 1994; Falkson and Falkson, 1996) as second- and first-line therapy, respectively, third-generation AIs, which inhibit aromatase activity by > 96%, show significant clinical efficacy benefits over these standard second- and first-line comparators (Buzdar et al, 1996a, 1998, 2001; Dombernowsky et al, 1998; Bonneterre et al, 2000; Kaufmann et al, 2000; Nabholtz et al, 2000; Bonneterre et al, 2001; Mouridsen et al, 2001).

In contrast, direct comparison of the third-generation AIs anastrozole and letrozole has shown that although letrozole suppresses aromatase activity, oestrone and oestrone sulphate levels to a greater degree than anastrozole, these differences in

| ITT population | Anastrozole (n = 357) | Letrozole (n = 356) | P-value |
|----------------|----------------------|--------------------|--------|
| Median TTP* (months) | 5.7 | 5.7 | 0.920 |
| Median TTF (months) | 5.6 | 5.6 | 0.761 |
| Median OS (months) | 20.3 | 22.0 | 0.624 |
| Objective response (%) | | | |
| Total population | 12.3 | 19.1 | 0.014 |
| HR+ve subgroup | 16.8 | 17.3 | NA |
| Unknown receptor status subgroup | 8.4 | 20.8 | NA |

* TTP: primary end point; ITT = intention to treat; TTF = time to disease progression; TTF = time to treatment failure; OS = overall survival.

Table 3 Efficacy data in patients randomised to anastrozole or letrozole (Rose et al, 2002)
potency do not translate to clinically significant differences in the efficacy of these agents for the second-line treatment of hormone-sensitive advanced breast cancer (Rose et al., 2002).

The fact that these marginal differences in potency between anastrozole and letrozole do not appear to produce clinically relevant differences in efficacy suggests that there may be a threshold effect for aromatase inhibition/oestrogen suppression beyond which no further improvements in clinical efficacy can be gained. Since the potency of fadrozole, aminoglutethimide and fadrozole fell below this threshold, the third-generation AIs show clinical efficacy benefits relative to these older agents. Of note, however, is that although clinical efficacy may be unaffected by small differences in potency, this does not preclude the fact that small differences in oestrogen suppression may lead to differences in side-effect profiles, especially with respect to cardiovascular end points or effects on bone mineral density, and this is more likely to become apparent during longer-term treatment as these drugs move into the adjuvant setting.

CONCLUSION

The third-generation AIs are more potent inhibitors of the aromatase enzyme and cause greater oestrogen suppression than older agents such as aminoglutethimide, fadrozole and formestane. This is linked to an increase in the clinical efficacy of the third-generation AIs relative to the previous standard comparators in both the second- and first-line settings. In contrast, small changes in potency between anastrozole and letrozole are not associated with clinically relevant differences in their efficacy in the treatment of hormone-sensitive advanced breast cancer, suggesting the existence of a threshold of oestrogen suppression above which no further improvements in clinical efficacy can be gained.
