Employing a Keldysh-Eilenberger technique, we theoretically study the generation of a spontaneous supercurrent and the appearance of the $\varphi_0$ phase shift parallel to uniformly in-plane magnetized superconducting interfaces made of the surface states of a three-dimensional topological insulator. We consider two weakly coupled uniformly magnetized superconducting surfaces where a macroscopic phase difference between the $s$-wave superconductors can be controlled externally. We find that, depending on the magnetization strength and orientation on each side, a spontaneous supercurrent due to the $\varphi_0$-states flows parallel to the interface at the junction location. Our calculations demonstrate that nonsinusoidal phase relations of current components with opposite directions result in maximal spontaneous supercurrent at phase differences close to $\pi$. We also study the Andreev subgap channels at the interface and show that the spin-momentum locking phenomenon in the surface states can be uncovered through density of states studies. We finally discuss realistic experimental implications of our findings.

I. INTRODUCTION

The topological insulator (TI) is a new state of matter with revolutionary prospects in topological superconducting spintronics and topological quantum computation. The topological insulators rely mainly on strong spin-orbit couplings and possess conductive surfaces, while showing insulating aspects in their bulk. Subsequently, TIs provide unique realistic platforms to study robust quantum relativistic phenomena such as spin-momentum locking and quantum spin Hall effect. The spin direction of a moving particle at the surface of a three-dimensional (3D) TI in the presence of time-reversal symmetry is rigidly locked to its momentum direction. Due to the spin-momentum locking phenomenon, the induction of superconductivity and magnetism in the surface of a TI is predicted to serve as an unprecedented condensed matter platform that supports odd-frequency, topological superconductivity, and Majorana fermions. In order to fabricate superconducting and magnetic surface states, one can proximitize the surface channels with a superconductor and ferromagnet, respectively. The proximity-induced superconductivity and magnetism in the surface states are externally controllable through manipulating their inducers. It is worth mentioning that the spin-orbit coupling in the presence of superconductivity and magnetism can result in intriguing spin-dependent phenomena in various materials even in systems with strong nonmagnetic scatterings.

In recent experiments on the quantum transport through TI surface states reported by different groups, it has been concluded that a proper theoretical framework, describing all kinds of samples including disordered ones, is an approach that accommodates the possibility of the presence of nonmagnetic scattering resources. To provide such a theoretical framework, the quasiclassical approach in the equilibrium and nonequilibrium states was generalized for 3D TI surface states with different levels of the density of nonmagnetic impurities in the presence of superconductivity and magnetism with arbitrary magnetization patterns. This approach was employed to study TI-based diffusive Josephson configurations involving chiral helical magnetizations and the Edelstein phenomenon at the surface states. It was theoretically shown that well-controlled $0-\pi$ supercurrent reversals, $\varphi_0$ junctions, and proximity-induced vortices are accessible through the spin-momentum locking phenomenon and magnetoelastic effect. Also, several works have demonstrated that the spin-momentum locking phenomenon in the surface states of 3D TIs plays crucial roles independently of the amount of nonmagnetic impurities present in these channels.

The spontaneous surface flow of currents can occur in the context of $^3$He-A superfluid. Also, the unconventional superconductors in proper situations host surface states and spontaneous currents parallel to interfaces. This phenomenon has theoretically been studied in several systems including Josephson junctions made of $s$-wave/$d$-wave superconductors with different crystallographic orientations, chiral superconductors, and ferromagnetic layers coupled to the unconventional superconductors. Nonetheless, the experimental observation of spontaneous supercurrents at the surfaces of chiral superconductors is still elusive partially due to the Meissner effect and strong disorders that may exist at the surfaces.

In this paper, we make use of the Eilenberger equation derived in Ref. to analyze supercurrent flows at the interfaces of uniformly magnetized superconducting surface states of 3D TIs. We consider a 2D Josephson weak-link configuration made of surface channels of a 3D TI with an externally controllable superconducting phase difference $\varphi$ and uniform in-plane magnetizations in each segment.
depicted in Fig. 1. Note that the superconductivity inductor electrodes are spin-singlet superconductors. We show that when the magnetization strength within the left and right sides of the contact are unequal and perpendicular to the interface, a spontaneous supercurrent flows along the junction interface, where its direction and amplitude can be controlled through the extrinsic \( \varphi \) applied perpendicular to the interface. Our results demonstrate that the maximum value of the spontaneous current can be achieved at phase differences close to \( \varphi = \pi \). We justify our findings by calculating the phase relation of spontaneous supercurrent components along two opposite trajectories parallel to the junction interface. The observation of the predicted spontaneous supercurrent is direct evidence of the rigid spin-momentum locking phenomenon in the surface states\(^{25–27,29,30,32} \). Furthermore, we calculate the density of states (DOS) at the interface and discuss how the strength and direction of magnetizations can alter Andreev bound states in such junctions that in turn reveal the role of strong spin-momentum locking in the surface states of a 3D TI.

The paper is organized as follows. We first explain the setup considered and derive proper Green’s function describing the system in Sec. II. Next, using the Green’s function obtained, we calculate the spontaneous supercurrent along the junction interface of the Josephson weak-link configuration and discuss the phase relation of its components. We also calculate the DOS and the Andreev subgap states for various values of \( \varphi \) and magnetization orientations. We support our numerical findings by Riccati-parametrizing the Green’s function and deriving analytical expressions for the Andreev bound states in different situations. We finally give concluding remarks in Sec. III.

II. METHOD AND RESULTS

In order to analyze the spontaneous supercurrent flow along a uniformly in-plane magnetized interface made of surface channels of a 3D TI, we consider a Josephson weak-link shown in Fig. 1. The superconductivity and magnetism are both extrinsically induced in the surface states through \( s \)-wave spin-singlet superconductors and ferromagnetic thin films, respectively, and therefore can be calibrated externally. The Cooper pair wave-function \( \Psi \) inside the ferromagnetic layer decays and oscillates as a function of location, i.e., \( \Psi \propto \Delta \exp(-z/\xi_f) \cos(z/\xi_f) \), in which \( \Delta \) is the superconducting order parameter inside the bulk superconductor and \( \xi_f \) is a characteristic length given by \( \xi_f = \sqrt{D/\hbar} \) in a diffusive ferromagnet with the diffusive constant \( D \) and exchange field \( \hbar \). Thus, the thickness of the ferromagnetic layers should be properly chosen so that the superconductivity survives at the surface states. The orientation of magnetization induced in the surface channels \( \hat{h}_{l,r} \) can be rotated by applying an external magnetic field. To fabricate the double ferromagnetic setup depicted in Fig. 1, one can use different magnetic elements or compounds that respond differently to an externally applied magnetic field. For example, Py is a weak ferromagnet while LCMO is strong. When subjected to an external magnetic field, the magnetization of LCMO rotates reluctantly compared to Py\(^{54} \) so this constitutes favorably misaligned magnetizations. The superconducting phase difference \( \varphi = \varphi_\ell - \varphi_r \) can be controlled by passing a tuneable supercurrent through the top superconducting electrodes \( \theta_{l,r} \) are macroscopic phases of left and right superconductors). The two segments of the weak-link are separated by an insulator barrier along the \( y \) axis and the junction resides at \( x = 0 \).

To study the supercurrent flow in the weak-link Josephson structure, we follow Ref. 26, where the Usadel\(^{25} \) and Eilenberger\(^{56} \) techniques were generalized for the surface channels of a 3D TI in the presence of superconductivity and magnetism with different amounts of nonmagnetic impurities. Without losing the generality of our main conclusions, we utilize the Eilenberger equation\(^{26} \) throughout the paper:

\[
\frac{\alpha}{2} \{ \eta, \nabla \hat{g} \} = \left[ \hat{g}, \omega_n \hat{\tau}^\pm + i \hbar \mathbf{r} \cdot \mathbf{\sigma} \hat{\tau}^\pm + i \mu \eta \cdot \mathbf{n}_F + i \Delta (r) + \frac{\langle \hat{g} \rangle}{\tau} \right]
\]

![FIG. 1.](https://example.com/figure1.png)

**FIG. 1.** (Color online) Schematic of the TI-based Josephson weak-link junction considered. The superconductivity and magnetism are induced in the surface states of the 3D TI by virtue of the proximity effect. The macroscopic phases of the left and right superconductors \( \theta_{l,r} \) can be controlled externally. The orientation of the uniform in-plane magnetization induced in the surface states \( \hat{h}_{l,r} \) also can be calibrated through an external magnetic field. The left and right segments are separated by an insulator at \( x = 0 \), constituting an interface along the \( y \) axis. We assume that a phase gradient is applied across the junction normal to the interface and consider two trajectories in the \( xy \) plane, parallel with the interface, marked by \( A \) and \( B \) arrows to analyze the supercurrent flow parallel to the junction interface along the \( y \) axis.
where \( \hat{\eta} = (\hat{\sigma}^y, \hat{\sigma}^z), \hat{\tau}^\pm = \hat{\tau}^x \pm i \hat{\tau}^y, \Delta(r) = \hat{\sigma}^0(\Delta(r)\hat{\tau}^+ + \Delta^*(r)\hat{\tau}^-)/2, \) and \( r \) denotes the spatial dependence of quantities. The total Green’s function \( \check{g} \) has four components \( f, g, \check{f}, \check{g} \) that determine the physical properties of a system. Here \( \alpha \) represents the strength of the Rashba spin-orbit coupling available at the surface channels, \( h \) is the exchange field induced in the surface states, \( \mathbf{p}_F = \mathbf{p}_F/|\mathbf{p}_F| \) is a unit vector in the direction of momentum \( \mathbf{p}_F \) at the Fermi level, \( \omega_n = (2n+1)\pi T \) is the Matsubara frequency, \( T \) is the temperature, and \( n \in \mathbb{Z} \). The vector \( \hat{\sigma} \) is composed of Pauli matrices and used for the spin space while \( \hat{\tau} \) denotes the particle-hole space. The parameter \( \tau \) describes the mean-free-path time of moving quasiparticles in the presence of nonmagnetic impurities. Note that in the ballistic regime \( 1/\tau \to 0 \) and to simplify our calculations we neglect the term \( \langle g \rangle/\tau \) without losing the generality of our main conclusions. The Eilenberger equation (1) should be supplemented by a normalization condition, i.e., \( \check{g}\check{g} = 1 \), to provide correct solutions.

To appropriately describe the physics of the interface, we consider Ansats of type \( a^r_i + b^r_i e^{-i k \cdot r}, x > 0 \) and \( a^l_i + b^l_i e^{+i k \cdot r}, x < 0 \) to the solutions of the Green’s function components (\( i = 1–4 \) represents a specific component) on the right and left sides of the weak-link, respectively.\(^{57–60} \) We match the solutions at \( x = 0 \) where the two segments are weakly connected, derive analytically the corresponding Green’s function, and eventually extract results by numerically integrating over the Matsubara frequency. To obtain \( a^r_i, b^l_i \) coefficients, we substitute the introduced Ansatzs into the Eilenberger equation (1), make use of the normalization condition \( \check{g}\check{g} = 1 \), and assume that the solutions far enough away from the interface reduce to bulk solutions. Following this approach, we find suitable solutions to the components of the Green’s function \( x > 0 \):

\[
\begin{align*}
\check{g}_r(\omega_n) &= \frac{i\omega_n + h_r}{\sqrt{(i\omega_n + h_r)^2 - \Delta_r^2}} + b_r e^{-i \omega_n r}, \quad (2a) \\
\check{f}_r(\omega_n) &= \frac{\Delta_r}{\sqrt{(i\omega_n + h_r)^2 - \Delta_r^2}} + \frac{2b_r \Delta_r e^{-i \omega_n r}}{2(i\omega_n + h_r) - i\alpha_r k_r}, \quad (2b) \\
\check{f}_l(\omega_n) &= \frac{-\Delta^*_r}{\sqrt{(i\omega_n + h_r)^2 - \Delta_r^2}} + 2b_l \Delta^*_r e^{-i \omega_n r}, \quad (2c) \\
\check{g}_l(\omega_n) &= \frac{-i\omega_l - h_l}{\sqrt{(i\omega_l + h_l)^2 - \Delta^*_l}} - b_l e^{-i \omega_l r}. \quad (2d)
\end{align*}
\]

in which wavevector \( k_r = 2\pi r^{-1} \sqrt{-((i\omega_n + h_r)^2 + \Delta_r^2)} \). To find solutions in the left segment \( x < 0 \), it suffices we follow the same procedure with replacing \( k \to -k \) and indices \( l \to r \). A generic solution at the interface can be given by invoking indices \( l, r \) for the Green’s function and parameters involved on the left and right sides of the junction shown in Fig. 1.

By matching the Green’s function of the left and right segments of the weak-link at the junction location \( x = 0 \), the Green’s function of the interface \( \check{g} \) can be expressed by the following \( g \) and \( f \) components:

\[
\begin{align*}
g(\omega_n) &= \frac{\alpha_r k_r \Omega_l \Delta_r e^{i\theta_r} i\omega_n(i\omega_n + h_l)(\alpha_l k_l \Omega_l \Delta_l e^{i\theta_l} i\omega_n(i\omega_n + h_r))}{2\Omega_l \Omega_r (i\omega_n + h_l)(i\omega_n + h_r) \{\Delta_r e^{i\theta_r} i\omega_n(2(i\omega_n + h_r) - i\alpha_r k_r) - \Delta_l e^{i\theta_l} i\omega_n(2(i\omega_n + h_l) + i\alpha_l k_l)\}}, \quad (3a) \\
f(\omega_n) &= \frac{\alpha_r k_r \Omega_l \Delta_r e^{i\theta_r} \Omega_l (i\omega_n + h_l)(i\omega_n + h_r) \{\Delta_l e^{i\theta_l} i\omega_n[-i\alpha_r k_r + 2(i\omega_n + h_r)] - \Delta_r e^{i\theta_r} i\omega_n[-i\alpha_l k_l + 2(i\omega_n + h_l)]\}}{\Omega_l \Omega_r (i\omega_n + h_l)(i\omega_n + h_r) \{\Delta_l e^{i\theta_l} i\omega_n[-i\alpha_r k_r + 2(i\omega_n + h_r)] - \Delta_r e^{i\theta_r} i\omega_n[-i\alpha_l k_l + 2(i\omega_n + h_l)]\}}, \quad (3b) \\
\Omega_{l,r} &= \sqrt{\Delta^2_{l,r} + \omega^2_n}, \quad k_{l,r} = \frac{2}{\alpha_{l,r}} \sqrt{\Delta^2_{l,r} - (i\omega_n + h_{l,r})^2}.
\end{align*}
\]

Because of the charge conservation law, the Green’s function at the interface, i.e., \( x = 0 \), is sufficient to study the supercurrent and thus we restrict our attention to \( \check{g}(x = 0) \). Note that the spatial dependence of the total Green’s function is given by Eqs. (2a)-(2d). The charge supercurrent is given through the \( g \) component of the total Green’s function:

\[
J_c(r) = 2ie\pi TN(0) \sum_{n \in \mathbb{Z}} \langle \nu_F g(\omega_n, r) \rangle, \quad (4)
\]

where the average \( \langle \ldots \rangle \) is taken over the direction of momentum, \( \nu_F \) is the Fermi velocity, and \( N(0) \) the density of states at the Fermi level.

To gain insight, let us first assume that \( h_{l,r} = 0, \theta_l = -\varphi/2, \theta_r = +\varphi/2, \) and \( \Delta_r \neq \Delta_l \). In this case, we find the following current phase relation to the supercurrent flowing in the \( x \) direction:

\[
J^x_c = 2e\pi TN(0) \times \sum_{n \in \mathbb{Z}} \frac{\Delta_r \Delta_l \sin \varphi}{\omega_n^2 + \sqrt{(\omega_n^2 + \Delta_r^2)(\omega_n^2 + \Delta_l^2)} + \Delta_r \Delta_l \cos \varphi}. \quad (5)
\]

As seen, the supercurrent in the \( x \) direction is directly proportional to the order parameter of the left and right superconductors, i.e., \( \Delta_l \) and \( \Delta_r \). Therefore, if one of the gaps is direction dependent, for example in a \( d_x - y^2 \)-wave superconductor [i.e., \( \Delta_l(\pm \Delta_r) = 0 \cos 2(\theta - \chi) \) where \( \nu_x = |\nu_F| \cos \theta \) is the particle velocity in the \( x \) direction and \( \chi \) is the angle that the \( d \)-vector makes with respect to an axis normal to the interface], we see that the supercurrent along the \( A \) and \( B \) trajectories (shown in Fig. 1) can be unequal in amplitude when \( \varphi \neq 0 \). This implies that a finite spontaneous supercurrent can flow along the interface when a nonzero superconducting phase difference is applied perpendicular to the junction.
the A trajectory is expressed by

$$J = J_0 \sum_{n \in \mathbb{Z}} \frac{2\mathcal{Z}\{S_1 \sin(\varphi_0 + \varphi) - \omega_n \sin \varphi + h_r \cos \varphi\}}{D},$$  \hspace{1cm} (6)$$

$$D = -2\left\{h_r (\mathcal{Z} \sin \varphi - S_1 \sin \varphi_0) + S_1 \omega_n \cos \varphi_0\right\} + 2S_2 \mathcal{Z} \cos (\varphi_0 + \varphi) - 2\omega_n \mathcal{Z} \cos \varphi + 2\omega_n \sqrt{\Delta^2 + \omega_n^2} + \Delta^2 + h_r^2 + \left((\Delta^2 + \omega_n^2)^2 + h_r^2 + 2h_r^2 (\omega_n^2 - \Delta^2) + 3\omega_n^2\right),$$  \hspace{1cm} (7a)$$

$$S_1 = \left[2\omega_n^2 (\Delta^2 + h_r^2) + (h_r^2 - \Delta^2)^2 + \omega_n^4\right]^{\frac{1}{2}},$$  \hspace{1cm} (7b)$$

$$S_2 = \left(\Delta^2 + \omega_n^2\right) + h_r^2 + 2h_r^2 (\omega_n^2 - \Delta^2),$$  \hspace{1cm} (7c)$$

$$\varphi_0^r = \frac{1}{2} \arg\left[\Delta^2 - (h_r + i\omega_n)\right],$$  \hspace{1cm} (7d)$$

$$\mathcal{Z} = \sqrt{\Delta^2 + \omega_n^2 + \omega_n}. $$  \hspace{1cm} (7e)$$

A phase relation similar to Eq. (6) can be obtained for the current density along the B trajectory by properly accounting for the magnetization direction. Figure 3(a) illustrates the spontaneous current densities along trajectories A and B as a function of \( \varphi \) for three different values of \( h_r = 0, 0.8\Delta_0, 1.6\Delta_0 \), and \( h_i = 0 \). Here we have defined \( J_0 = 2\pi TN(0) \). Note that the magnetization is oriented along the \( x \) axis perpendicular to the junction interface. As seen, the current densities along the \( A \) and \( B \) trajectories are identical when \( h_r = 0 \). This is starkly opposite to the cases where \( h_r \neq 0 \). We see that the current densities along the \( A \) and \( B \) trajectories are dissimilar and therefore cause a finite spontaneous current along the interface \( J_{tot} = J^A - J^B \neq 0 \). From Fig. 3(a) it is clear that \( J_{tot} \) is at a maximum at phases close to \( \varphi = \pi \) due to
the nonsinusoidal behaviour of the current density phase relations. The current densities are nonzero at zero phase difference when \( h_r \neq 0 \); namely the current density experiences a \( \varphi_0 \) phase shift in the presence of magnetization. From Eq. (6) it is apparent that the current density is nonzero at zero phase difference \( \varphi = 0 \) when \( h_r \neq 0 \). It is worth mentioning that the appearance of a \( \varphi_0 \) phase shift in the supercurrent has theoretically been discussed in various situations\(^{13,16,26,27,62–72}\) and observed in experiments\(^{73,74}\). In structures where the spin orbit mediated coupling is available, its interplay with a Zeeman(-like) field results in a supercurrent and observed in experiments\(^{73,74}\).

FIG. 4. (Color online) The density of states DOS(\( \varepsilon \)) as a function of the quasiparticles energy \( \varepsilon \) at the interface of weak-link \( x = 0 \). (a) We set \( h_r = h_l = 0 \) and vary the phase difference \( \varphi = 0, 0.3\pi, 0.6\pi, 0.8\pi, \pi \). In panel (b), we examine the effect of magnetization direction on the Andreev subgap states by setting \( h_l = 0, \varphi = \pi/2 \), and \( h_r = 0, \pm 0.5\Delta_0 \). (c) We consider opposite magnetization directions with identical intensities on the left and right sides of the weak-link \( h_l = h_r = 0.5\Delta_0 \) and vary the phase difference similarly to panel (a). In the coordinate system shown also confirm this fact.

One of the measurable physical quantities in the laboratory is the density of states. The DOS can be detected by STM experiments or through I-V characteristic curves in a tunneling spectroscopy experiment where \( dI / dV \) is proportional to the DOS. The DOS in the quasiclassical approach is accessible through the normal component of the total Green’s function, i.e., Eq. (3a):

\[
\text{DOS}(\varepsilon, r) = N(0) \text{Re} \left\{ g(\omega_n \rightarrow \varepsilon + i\delta, r) \right\},
\]  

in which we have introduced an infinitesimal imaginary number \( i\delta \) and, for convenience in our subsequent analyses, turn to the energy representation by substituting \( \omega_n \rightarrow \varepsilon + i\delta \). The imaginary part \( i\delta \) helps to account properly for the Green’s function poles. In Fig. 4 we plot the DOS as a function of normalized quasiparticle energy \( \varepsilon / \Delta_0 \) at the interface \( x = 0 \). Figure 4(a) illustrates the DOS where the phase difference \( \varphi \) between the two segments of the Josephson weak-link (see Fig. 1) is \( 0, 0.3\pi, 0.6\pi, 0.8\pi, \pi \). We also set \( h_l = h_r = 0 \) which is equivalent to a normal Josephson contact. At \( \varphi = 0 \), the DOS shows the usual BCS gap structure with a singularity at \( \varepsilon = \Delta_0 \). When we set \( \varphi \neq 0 \) a singularity appears at energies below the superconducting gap \( \varepsilon < \Delta_0 \). This singular point corresponds to an Andreev bound state due to the resonance of particle-hole conversions at the interfaces of left and right superconductors. The bound state moves to \( \varepsilon = 0 \) when the phase difference is maximum \( \varphi = \pi \). In Fig. 4(b), we set \( h_l = 0, \varphi = \pi/2 \) and plot DOS for \( h_r = 0, \pm 0.5\Delta_0 \). As seen, the nonzero magnetization in the right segment of weak-link shifts the Andreev subgap state to smaller or larger energies, depending on the magnetization direction. If we set opposite magnetization directions with identical strengths on opposite sides of the weak-link segments, i.e., \( h_l = -h_r \), the shift in the Andreev bound states induced by the direction of magnetization disappears and the Andreev subgap state at \( \varphi = \pi \) reoccurs at \( \varepsilon = 0 \).

To gain better insights, in what follows, we parametrize the Green’s function and derive an analytical expression for the Andreev bound states. To this end, we make use of a so-called Riccati parametrization scheme\(^{75}\) and define two propagators \( \gamma \) and \( \gamma^\ast \) so that the Green’s function is rewritten as follows:

\[
\hat{g} = \frac{1}{1 - \gamma \gamma^\ast} \begin{pmatrix} 1 + \gamma \gamma^\ast & +2\gamma \\ -2\gamma & -1 - \gamma \gamma^\ast \end{pmatrix}. \tag{9}
\]

Substituting the parametrized Green’s function into the Eilenberger equation, Eq. (1), two decoupled first-order differential equations for \( \gamma \) and \( \gamma^\ast \) appear. After some calculations, we find the following solutions to \( \gamma \) and \( \gamma^\ast \) at the interface from the right side of the weak-link \( x \to 0^+ \):

\[
\gamma_r = \frac{(\varepsilon + h_r) - \text{sgn}(\varepsilon + h_r)\sqrt{(\varepsilon + h_r)^2 - \Delta^2}}{\Delta e^{-i\theta_r}}, \tag{10a}
\]

\[
\gamma^\ast_r = \frac{(\varepsilon + h_r) - \text{sgn}(\varepsilon + h_r)\sqrt{(\varepsilon + h_r)^2 - \Delta^2}}{\Delta e^{i\theta_r}}. \tag{10b}
\]

Similar solutions are derived to \( \gamma \) and \( \gamma^\ast \) at the interface from \( x \to 0^- \). The Andreev bound states can be determined.
through the singularities in the normal component of the Green’s function as discussed earlier [see Eq. (8) and its associated results presented in Fig. 4]. Therefore, the singularities are solutions of $1 - \gamma \gamma = 0$ that result in:

$$
\cos \varphi = \frac{(h_l + \varepsilon)(h_r + \varepsilon)}{\Delta l \Delta r} + \left[\left(1 - \frac{(h_l + \varepsilon)^2}{\Delta l^2}\right)\left(1 - \frac{(h_r + \varepsilon)^2}{\Delta r^2}\right)\right]^{-\frac{1}{2}} = 0, \quad (11)
$$

where we invoked the left and right indices $l, r$ for the quantities of the left and right segments of the weak-link. By carrying out some calculations, we find the following relation to the Andreev bound states:

$$
\varepsilon_A = \Delta \cos \varphi / 2. \quad (13)
$$

This relation shows that the bound state at $\varphi = 0$ moves to the edge of the superconducting gap at $\varepsilon_A = \Delta$ and to zero energy when $\varphi = \pi$ in line with previous works on the conventional Josephson short junctions [57–60]. These results are consistent with our numerical calculations discussed in Fig. 4(a). We now set $h_l, h_r \neq 0$ and find the following relation for the Andreev bound states:

$$
\varepsilon_A = \frac{\mathcal{H}_\pm (1 - \cos \varphi) \pm \sin \varphi \sqrt{2\Delta^2 (1 - \cos \varphi) - \mathcal{H}^2}}{2(1 - \cos \varphi)}. \quad (14)
$$

We see that the general aspects of the latter expression are in full agreement with the numerical results presented in Figs. 4(b) and 4(c). If we set $\varphi = \pi$, the bound state occurs at $\varepsilon_A = (h_l + h_r)/2$. It is evident that if the magnetization directions in the left and right segments are opposite, $h_l = -h_r$, the bound state takes place at $\varepsilon = 0$ which is consistent with the DOS results presented in Fig. 4(c). The difference between the TI junction and a conventional one is the presence of strong spin-orbit coupling (or equivalently the spin-momentum locking), and therefore, the directional dependence discussed above is a direct consequence of the spin-momentum locking phenomenon. It is worth noting that not only can the DOS in an intrinsic spin-orbit coupled magnetic superconducting hybrid be magnetization direction dependent, but also the charge and spin supercurrents are found to be sensitive to the direction of magnetization [19–22, 76]. The DOS at maximum superconducting phase difference $\varphi = \pi$ in a diffusive Josephson junction peaks at zero energy due to the appearance of superconducting triplet correlations both in magnetic inhomogeneous [77] and spin-orbit coupled systems [76].

The spontaneous supercurrent explored here can be experimentally measurable through multiterminal devices [76]. Two transverse electrodes should be attached to the lateral edges of the two-dimensional topological insulator weak-link at $x = 0$ and $y = \pm W/2$ where $W$ is the junction width and we assumed $W \to \infty$ in our calculations (see Fig. 1). The transverse spontaneous current parallel to the junction interface discussed above injects charge current into the lateral leads and can induce a voltage drop between the lateral leads that is detectable in experiment [78]. By applying a voltage difference between these lateral electrodes, the DOS and thus the subgap bound states can be revealed in an $I$-$V$ measurement. When these signatures are detected in an experiment, a rotatable in-plane external magnetic field can confirm our findings. Our predictions are valid regardless of the density/strength of nonmagnetic impurity and scattering resources present at the surface channels. Also, to rotate the magnetization in the setup proposed, an in-plane external magnetic field suffices. Therefore, the impurity and Meissner obstacles pointed out in the introduction to experimentally observe the spontaneous currents at the surfaces of chiral superconductors are not relevant in the Josephson weak-link considered in this paper.

III. CONCLUSIONS

In conclusion, utilizing a recently generalized quasiclassical approach to superconducting magnetized surface states of a three-dimensional topological insulator (TI) [26, 27], we study supercurrent flows at the magnetic interface of a TI. We consider a Josephson weak-link with two uniformly in-plane magnetized segments, $h_l$ and $h_r$, where the magnetizations have nonzero components perpendicular to the interface. Our results reveal that a spontaneous supercurrent flows parallel to the interface at the junction location provided that $|h_l| \neq |h_r|$ and reaches its maximum when the phase difference $\varphi$ between the left and right segments is close to $\pi$. We also study the Andreev bound states in such a weak-link through the density of states both numerically and analytically. We Riccati-parametrize the Green’s function involved in our calculations and derive analytical expressions to the Andreev subgap states. We discuss the influences of the magnetization directions in the left and right sides of the Josephson weak-link on the Andreev bound states.
M.A. is thankful to I.V. Bobkova and A.M. Bobkov for useful discussions.
