(Received 11 February 2010; published 28 June 2010)

Dislocation assemblies exhibit a jamming or yielding transition at a critical external shear stress value \( \sigma = \sigma_c \). Here we study the heterogeneous and collective nature of dislocation dynamics within a crystal plasticity model close to \( \sigma_c \), by considering the first-passage properties of the dislocation dynamics. As the transition is approached in the moving phase, the first-passage time distribution exhibits scaling, and a related peak dynamical susceptibility \( \chi_2 \) diverges as \( \chi_2 \sim (\sigma - \sigma_c)^{-\alpha} \), with \( \alpha = 1.1 \). We relate this scaling to an avalanche description of the dynamics. While the static structural correlations are found to be independent of the external stress, we identify a diverging dynamical correlation length \( \xi \), in the direction perpendicular to the dislocation glide plane.

The mechanical behavior of crystalline solids subject to an external shear stress \( \sigma \) is controlled by a finite yield stress \( \sigma_c \). For stresses below it, only elastic or reversible deformation of the material takes place, while sustained plastic or irreversible deformation mediated by dislocation motion is observed for \( \sigma > \sigma_c \). The basic phenomenology of two states with different rheology is similar also for many amorphous materials ranging from foams to amorphous and granular media, even though the microscopic mechanisms responsible for a transition to “flow” are not yet well understood. The concept of jamming has been introduced to comprehend the observed phenomenology: In a finite region of the parameter space (spanned by control variables such as temperature, density, and an external force), due to a “cage effect,” or self-induced constraints on the motion of the system constituent particles, the phase space dynamics gets restricted, i.e., jammed [1–4]. For two-dimensional ensembles of crystal dislocations, a yielding transition at a finite \( \sigma_c \) has been established, even in the absence of any external sources of disorder [5]. The crucial mechanism here is the generation of effective disorder in the local stress field, due to constrained dislocation motion by the combined effect of the slip geometry and the long-range anisotropic dislocation-dislocation interactions. These are also manifest in the formation of metastable structures such as dislocation dipoles and walls.

On approaching the jamming transition from the moving phase, the dynamics generally becomes increasingly heterogeneous. A growing dynamical correlation length characterizing spatial and temporal correlations has been observed for granular systems [6,7], as well as on approaching the glass transition of molecular liquids and colloidal suspensions [8]. In this work, we consider dislocation jamming in a similar vein. Known features of the 2D discrete dislocation dynamics (DDD) model studied here are a relaxation of the strain rate or an Andrade law: Close to \( \sigma = \sigma_c \), it follows a power law \( \dot{\varepsilon} \sim t^{-\theta} \), \( \theta = 2/3 \) [5]. The steady state strain rate displays a nonlinear rheological behavior, \( \dot{\varepsilon} \sim (\sigma - \sigma_c)^\beta \), with \( \beta = 1.8 \) [5]. The model also reproduces the experimentally observed scale-free size distributions of avalanches of plastic deformation [9]. Similar DDD models are used also in many materials science applications [10]. The question is now whether one can establish the jamming or yielding transition as a second-order phase transition. This would imply the existence of a length scale, the correlation length, diverging at the transition point. The dislocation system nonequilibrium transition is particular, since the temperature is included only indirectly via the dislocation mobility and is thus irrelevant.

The avalanches exhibited by dislocation assemblies [9] are suitable candidates for fundamental “dynamical heterogeneities” or localized events. We define appropriate statistical quantities to characterize the dynamics via time-dependent first-passage probabilities, which measure the likelihood that a dislocation becomes liberated from the confining stress field over an observation scale. The first-passage distributions are found to display scaling close to the transition, and, analogously to other jamming systems, the peak value of a dynamical susceptibility and a dynamical correlation length grow on approach and diverge at \( \sigma = \sigma_c \). At the same time, static correlations describing the dislocation structures are found to be virtually independent of the external stress. We also connect the results to an avalanche description of the dynamics.

The DDD model represents a 2D cross section (xy plane) of a 3D single crystal with a single slip geometry [5,9,11]. The dislocations are straight parallel edge ones, with the dislocation lines along the z axis. The \( N \) pointlike dislocations glide along directions parallel to their Burgers vectors \( \vec{b}_n = s_n \vec{b}_1 \), with \( s_n = \pm 1 \) and \( \vec{b}_1 \), the unit vector in the
x direction. Equal numbers of dislocations with positive and negative Burgers vectors are considered. Dislocation climb is excluded for simplicity. The dislocations interact with each other through their anisotropic long-range stress fields, \( \sigma (\mathbf{r}) = D b x (x^2 - y^2)/(x^2 + y^2)^2 \), where \( D = \mu/2\pi(1-\nu) \), with \( \mu \) the shear modulus and \( \nu \) the material’s Poisson ratio. The dynamics is taken to be overdamped with a linear force-velocity relation, with the equations of motion

\[
\frac{\chi_d v_n}{b} = s_n b \left[ \sum_{m \neq n} s_m \sigma_m (\mathbf{r}_{nm}) + \sigma \right],
\]

where \( v_n \) is the velocity of the \( n \)th dislocation, \( \chi_d \) is the dislocation mobility, \( s_n \) is the sign of the Burgers vector of the \( n \)th dislocation, and \( \sigma \) is the applied external shear stress. The long-range interaction forces are computed by imposing periodic boundary conditions in both \( x \) and \( y \) directions. The equations of motion are integrated numerically with an adaptive step size fifth-order Runge-Kutta algorithm in dimensionless units by measuring lengths in units of \( b \), times in units of \( 1/(\chi_d Db) \), and stresses in units of \( D \). If the distance between two dislocations of opposite sign gets smaller than \( 2b \), they are removed, a process reminiscent of the annihilations occurring in real crystals.

The simulations are started from a random initial configuration of \( N_0 \) dislocations within a square cell of linear size \( L \). The system is first let to relax with \( \sigma = 0 \), until it reaches a metastable dislocation arrangement. During this relaxation, a significant fraction gets annihilated. We take \( L = 200b \) and \( 300b \), with \( N_0 = 1600 \) and 3600, respectively. After the relaxation, the external stress is switched on, and the evolution of the system is monitored. For \( \sigma > \sigma_c = 0.025 \) [12], the system eventually reaches a steady state, with the strain rate \( \dot{\epsilon} = -\sum_n b_n v_n \) fluctuating around a constant mean value. The steady state consists of \( N = 375 \) dislocations for \( L = 200b \) and \( N = 850 \) for \( L = 300b \) [13].

To characterize the heterogeneous dynamics we first consider the first-passage time \( \langle t_{fp} \rangle \) distribution of dislocations in the moving steady state. \( t_{fp} \) is defined as the time at which a dislocation first moves across a distance \( l \) from some initial position and thus becomes liberated from a confining stress field at this scale. Given the nonlinear stress dependence of the steady state strain rate [5], the mean first-passage time is expected to behave like \( \langle t_{fp} \rangle \sim l/\langle \dot{\epsilon} \rangle \sim l(\sigma - \sigma_c)^{-\beta} \). Assuming \( \delta t_{fp} \sim \langle t_{fp} \rangle \), one can write

\[
P(t_{fp}; l, \sigma) = \frac{1}{l(\sigma - \sigma_c)^{-\beta}} \mathcal{F} \left[ \frac{l - l(\sigma - \sigma_c)^{-\beta}}{l(\sigma - \sigma_c)^{-\beta}} \right].
\]

Figure 1 shows a data collapse according to Eq. (2) with \( \beta = 1.8 \), in good agreement with the scaling of strain rate with the applied stress [5]. The scaling function \( \mathcal{F}(x) \) exhibits a maximum and a tail, which does not contribute much to the typical escape characteristics.

A cumulative version of \( P(t_{fp}) \) is the instantaneous self-overlap order parameter [7] \( Q(l, \tau) = 1/N \sum_{n=1}^{N} w_n \), where \( w_n = 1 \) if the displacement of dislocation \( n \) remains less than \( l \) across the time interval \( t \rightarrow t + \tau \) and equals 0 otherwise. The first two moments

\[
Q(l, \tau) = \langle Q(l, \tau) \rangle,
\]

\[
\chi_4(l, \tau) = N[\langle Q(l, \tau)^2 \rangle - \langle Q(l, \tau) \rangle^2] \quad (4)
\]

of \( Q(l, \tau) \) (calculated from sample-to-sample fluctuations) are then used to characterize the dynamics. As is customary for similar problems, we consider here only samples that are still active at the observation time [14]. By construction, \( Q(l, \tau) \) decays from one to zero as a function of \( \tau \), while the four-point dynamic susceptibility \( \chi_4(l, \tau) \) exhibits a peak at an intermediate \( \tau = \tau^*_l \) and vanishes for both early and late times; see Fig. 2. \( Q^* = Q(l, \tau^*_l) \approx 0.5 \) is

\[
\begin{align*}
\chi_4(l, \tau) = N & \left[ \langle Q(l, \tau)^2 \rangle - \langle Q(l, \tau) \rangle^2 \right] \\
F(l, \tau) = & \int_0^\infty dt_{fp} P(t_{fp}; l, \sigma) \langle t_{fp} \rangle \chi_4(l, \tau^*_l)
\end{align*}
\]

FIG. 2 (color online). Top: The average self-overlap order parameter \( Q(l, \tau) \) for various values of \( \sigma \) as a function \( \tau \), for \( l = 1 \). Bottom: The corresponding four-point dynamic susceptibilities \( \chi_4(l, \tau) \). The inset shows evidence of a data collapse of \( \chi_4(l, \tau) \), obtained by rescaling the data with the scaling forms of \( \langle t_{fp} \rangle \) and \( \chi_4 \). with \( \alpha = 1.1 \) and \( \beta = 1.8 \).
nearly a constant. The peak value $\chi_4^*\equiv\chi_4(l,\tau)$ depends on 
the proximity of the critical stress $\sigma_c$, and has been argued to 
be related to the typical number of particles (here dislocations) in 
a correlated fast-moving domain or heterogeneity [7].

In the simulations, we observe a growing $\chi_4^*$ as $\sigma$ is 
approached from above, with an apparent divergence at 
$\sigma = \sigma_c = 0.025$; see Fig. 3. For external stresses $\sigma \leq 0.07$, the 
stress dependence of $\chi_4^*$ can be characterized by a 
power law $\chi_4^* \sim (\sigma - \sigma_c)^{-\alpha}$, with $\alpha = 1.1$. This result 
does not exhibit any significant $l$ dependence. The scaling 
of $\chi_4^*$ can be connected to the avalanche dynamics close to 
the transition by directly computing the variance of $Q(l,\tau)$ at $\tau_c^*$. 
Consider the distribution of avalanche sizes $s$ with a 
$\sigma$-dependent cutoff: $P(s) = s^{-\epsilon} f([s/(\sigma - \sigma_c)]^{-\gamma})$. By 
assuming that the number of dislocations $n$ swept to a 
distance $l$ during an avalanche obeys $\langle n \rangle \sim \langle s \rangle$ and using 
the condition $\bar{M}(n) = N/2$ (arising from the observation that $Q^* = 0.5$) to estimate the number $M$ of independent 
avanches occurring up to the delay time $\tau_c^*$, we 
obtain $\chi_4^* = N(\delta Q^*)^2 \sim N(\bar{M}(n)/N)^2 \sim \langle n \rangle/2 \sim (\sigma - \sigma_c)^{1-\gamma}$. As $\langle n \rangle$ grows on approaching $\sigma_c$, the number 
$M$ of heterogeneities contributing to $\chi_4^*$ decreases: An 
estimate for $L = 300b$ leads to $M = 19$ for $\sigma = 0.06$ 
and $M = 6$ for $\sigma = 0.037$. As the avalanche size exponent 
is close to the mean field $\tau = 1.5$ [11], $\alpha = 1$ would 
give $\gamma = 2$, again consistent with the mean-field-like 
scenario [15]. Incorporating a frictional stress $\sigma_F$ to model 
the Peierls barrier (relevant for bcc metals), the same 
results hold qualitatively true up to a $\sigma_F$ comparable to 
the yield stress $\sigma_c$. The yield stress for $\sigma_F > 0$ is simply 
shifted such that $\hat{\sigma}_c = \sigma_c + \sigma_F$ [16].

To further explore the possibility of identifying a divergent 
nonequilibrium correlation length, we consider the 
conditional probability $g_d(\tilde{r}, \tilde{l}) = P[w(\tilde{r}, \tau_c^*) = \tilde{l}]W(\tilde{l}, \tau_c^*, 0) = w(l, \tau_c^*, 0) = 0]$ 
that a dislocation at a position $\tilde{r}$ has 
moved at least a distance $l$ up to a delay time $\tau_c^*$, 
given that a dislocation at the origin has done so. $g_d(\tilde{r}, l)$ 
provides a measure of the spatial structure of the typical heterogeneities 
contributing to $\chi_4^*$. Figure 4(a) and 4(b) shows 
examples of this dynamical correlation function for stress 
values $\sigma = 0.06$ and $\sigma = 0.04$, respectively. We focus 
here for simplicity on the case $l = 1$. Notice that closer 
to jamming, correlations clearly extend further in the $y$ 
direction, while we could not identify a clear trend in the $x$ 
direction. At the same time, the static density-density 
correlation function $g(\tilde{r})$, computed from snapshots of 
the dislocation configurations in the steady state, does 
not show any significant dependence on $\sigma$ [17,18]. To 
estimate the dynamical correlation length, we fitted an 
exponential function $\exp(-y/\xi_y)$ to the $g_d(\tilde{r})$ data 
averaged over a narrow strip along the $y$ direction [19]. 
This leads to a divergent stress dependence of 
$\xi_y \sim (\sigma - \sigma_c)^{-\nu_y}$, with $\nu_y \approx 1$; see Fig. 5. A similar analysis in the $x$ 
direction is less conclusive. Because of the tendency 
of dislocations to form wall-like structures, the statistics 
is significantly worse in the $x$ direction, and no clear trend is 
visible for the evolution of $\xi_x$ with $\sigma$ (inset in Fig. 5): $\xi_x$ 
appears to have a relatively large stress-independent value 
around $\xi_x = 35b$ [20]. In 3D DDD simulations [21], 
avanches have been observed to be characterized by a lamellar 
shape, something that could be related to this large 
value of $\xi_x$. Indications of similar anisotropic avalanches 
have been observed in a continuum model of yielding [22].

FIG. 5 (color online). Main figure: The dynamic correlation
length \(\xi_y\) in the \(y\) direction, exhibiting a power law divergence
close to \(\sigma_c\). Inset: The dynamic correlation length \(\xi_x\) in the \(x\) direction. The length scale parameter \(l = 1\) is used.
Notice also that the observed scaling of \(\xi_y\) is consistent
with the mean field cutoff scaling of the avalanche size
distribution, assuming that \(\xi_y\) measures the linear size of a
typical avalanche in the \(y\) direction.
In summary, we have shown that the dislocation jamping
transition is accompanied by a divergent dynamic
susceptibility and a divergent correlation length. This scal-
ing, which we relate to the avalanche dynamics of the
system, is purely dynamical in nature: The static correla-
tion function characterizing the dislocation structures does
not exhibit any significant dependence on \(\sigma\). The observed
exponent values \(\alpha = \nu_j = 1\) indicate that the heterogene-
ities are compact and characterized by a single diverging
correlation length in the \(y\) direction, thus clearly demon-
strating that the dislocation jamming transition is indeed a
true nonequilibrium second-order phase transition. It
would be interesting to test similar avalanche-based ideas
also for plasticity of amorphous solids [23]. Notice that,
despite similarities with other relevant systems such as
granular media, there are also significant differences: In
the dislocation system the dynamics stops due to the for-
formation of various metastable dislocation structures (di-
poles, walls, and more complicated multipolar structures)
 arising from the combination of anisotropic long-range
dislocation-dislocation interactions and restricted disloca-
tion motion along a single slip direction. On the other hand,
e.g., in granular systems, jamming takes place when grains
get stuck by short-range contact forces within cages
formed by their nearest neighbors, a process that is not
accompanied by any large scale grain structures. The ob-
servation that in the present case the results seem to be
independent of \(l\) close enough to the transition suggests
that, contrary to many other systems where \(l\) needs to be
tuned to a specific value related to an underlying “cage
size,” such a typical microscopic length does not exist
here. This indicates that the same scale-free property
would apply also for the force landscape experienced by
the dislocations, with the first-passage properties related to
the time it takes for the force landscape to deform on the
observation scale, due to the avalanche dynamics.
