1. Introduction

Efficient green or red OLEDs with pure color CIE coordinates have been reported\(^{3-4}\) and blue emitters with less power consumption in organic optoelectronics have also been broadly studied.\(^{5-6}\) However, there is need for long-lifetime blue emitters with pure colour CIE coordinates due to wide band gaps (\(E_g\)), which require limited \(\pi\)-conjugation length.\(^{7-9}\) Simultaneous carrier injection into a blue-emissive layer becomes very difficult due to its wide \(E_g\), resulting in a decrease in device efficiency.\(^{10,11}\) Therefore, for OLED applications, highly efficient and low-cost blue OLEDs are of urgent demand. The external quantum efficiency (\(\eta_{\text{ex}}\)) can be deduced from the following equation: \(\eta_{\text{ex}} = \eta_{\text{IQE}} \times \eta_{\text{out}} = \eta_{\text{rec}} \times \eta_{\text{PL}} \times \eta_{\text{rec}} \times \eta_{\text{out}}\), where \(\eta_{\text{IQE}}\) is the internal quantum efficiency, \(\eta_{\text{out}} \approx (1/2\pi)^2\) is the light out-coupling efficiency (\(n = 1.5, \eta_{\text{out}} \approx 20\%\)), \(\eta_{\text{rec}}\) is the electron-hole recombination efficiency (100%), \(\eta_{\text{PL}}\) is the photoluminescence efficiency and \(\eta_{\text{rec}}\) is the utilization efficiency. The two key parameters \(\eta_{\text{PL}}\) and \(\eta_{\text{rec}}\) required for high \(\eta_{\text{ex}}\) can be tuned by altering the emitter molecular design.\(^{12}\)

A blue-emissive material with high triplet energy (\(E_T\)) may be employed as a host for green OLEDs.\(^{13-16}\) However, the high triplet energy enables green emitters to harvest the triplet energy of a blue emitter; also, efficient non-doped blue emitters are not suitable as hosts for phosphorescent OLEDs due to their low \(E_T\) as well as poor carrier transport properties.\(^{17}\) Moreover, efficient hosts for green emitter exhibit low efficiency when they are used as emissive materials in blue OLEDs.\(^{18-20}\) Hence, efforts are still required to achieve efficient OLEDs based on blue emissive materials.

Therefore, to develop dual-functional emissive materials, \(i.e.,\) emitters for blue OLEDs and hosts for green OLEDs, synthesis of molecules with donor (D)/acceptor (A) (electron/hole transport moieties) configuration has gained interest. To achieve deep blue emission, the donor–acceptor (D–A) molecule should have relatively weak charge transfer properties since a strong D–A geometry can induce red-shifted emission. In addition, the singlet–triplet splitting should be small to ensure that the triplet-excited state energy is high enough to excite the green phosphorescent dopant.

With our continuous interest to synthesize efficient n-type imidazole derivatives as OLED emitters,\(^{21-23}\) herein we report...
the synthesis of \((E)-4^\prime-(1-(4-(2-(1-(4-morpholinophenyl)-1H-phenanthro[9,10-d][imidazol-2-yl]vinyl)phenyl)-1H-phenanthro[9,10-d][imidazol-2-yl]-N,N-diphenyl-[1,1'-biphenyl]-4-amine (SMPI-TPA) and \((E)-4-(4-(2-(4-(9H-carbazol-9-yl)phenyl)-1H-phenanthro[9,10-d][imidazol-1-yl]styryl)-1H-phenanthro[9,10-d][imidazol-1-yl]phenyl)morpholine (SMPI-Cz) derivatives and utilize them as blue emitters in non-doped devices and hosts for green OLEDs. These derivatives exhibit higher stability with balanced injection property, leading to excellent device performances.

2. Materials and measurements

The structure of emissive materials was confirmed by \(^1\text{H}\) and \(^{13}\text{C}\) NMR spectroscopies and mass spectrometry, recorded using a Bruker spectrometer (400 MHz) and Agilent (LCMS VL SD), respectively. Redox potentials were measured using a potentiostat CHI 630A electrochemical analyzer. The Lambda SD, respectively. Redox potentials were measured using a potentiostat CHI 630A electrochemical analyzer. The Lambda

2.1. Theoretical calculations

Using the Gaussian 09 software package,\(^{24}\) the electron density on frontier molecular orbitals of SMPI-TPA and SMPI-Cz was identified.

2.2. Devices fabrication

OLEDs with SMPI-TPA and SMPI-Cz emitters were fabricated by vacuum deposition at 5 × 10\(^{-6}\) Torr on a precleaned ITO substrate with 20 \(\Omega\) per square resistance (rate −0.1 nm s\(^{-1}\)). LiF and Al were also evaporated thermally on the organic layer and the thickness was measured using a quartz crystal thickness monitor. A series of fabricated devices with multilayer configuration of ITO/NPB (30 nm)/TPBI (20 nm)/LiF (1 nm)/Al (200 nm) were recorded using a Keithley 2400 sourcemeter.

2.2.1. Synthesis of 2-(4-nitrostyryl)-1-(4-morpholinophenyl)-1H-phenanthro[9,10-d][imidazole]. Phenanthrenequinone (2.08 g, 10 mmol), 4-nitrocinnamaldehyde (1.51 g, 10 mmol), 4-morpholinobenzenamine (4.65 g, 50 mmol) and ammonium acetate (3.08 g, 40 mmol), all in acetic acid (25 mL), were refluxed (120 °C; 12 h; \(N_2\) stream). Then, 2-(4-nitrostyryl)-1-(4-morpholinophenyl)-1H-phenanthro[9,10-d][imidazole] was purified and used for further analyses (Scheme S1). Anal. calcd C\(_{33}\)H\(_{26}\)N\(_4\)O\(_3\): C, 75.26; H, 4.86; N, 10.65. \(^1\text{H}\) NMR (400 MHz, CDCl\(_3\)); \(\delta\) 2.97 (6H, 3.48), 3.58 (4H), 6.54 (d, J = 8.8 Hz, 2H), 7.13 (d, J = 16.0 Hz, 1H), 7.18 (d, J = 15.2 Hz, 1H), 7.32 (s, 2H), 7.52 (d, J = 8.6 Hz, 2H), 7.71–7.83 (m, 6H), 8.02 (s, 1H), 8.13 (d, J = 8.4 Hz, 2H), 8.51 (d, J = 7.2 Hz, 1H). \(^1\text{C}\) NMR (100 MHz, CDCl\(_3\)); \(\delta\) 47.33, 62.42, 114.68, 119.43, 119.86, 120.31, 120.78, 121.12, 121.44, 122.85, 123.12, 123.85, 124.02, 124.70, 124.85, 126.17, 126.26, 125.39, 126.67, 126.19, 126.44, 126.53, 126.74, 129.72, 131.43, 145.45, 166.73. 3. Results and discussion

As depicted in Scheme S1, the blue emitters used as hosts for green OLEDs, namely, (E)-4’-((1-4-(2-(1-(4-morpholinophenyl)-1H-phenanthro[9,10-d]imidazol-2-yl)vinyl)phenyl)-1H-phenanthro[9,10-d]imidazol-2-yl)-N,N-diphenyl-[1,1’-biphenyl]-4-amine (SMPI-TPA) and (E)-4-(4-(2-(4-(2-(4-(9H-carbazol-9-yl)phenyl)-1H-phenanthro[9,10-d]imidazol-1-yl)styryl)-1H-phenanthro[9,10-d]imidazol-1-yl)phenyl)morpholine (SMPI-Cz) were prepared from phenanthrenequinone (0.416 g, 2 mmol), 4’-(diphenylamino)biphenyl-4-carbaldehyde (SMPI-TPA)/4-(9H-carbazol-9-yl)benzaldehyde (SMPI-Cz), 4-(E)-2-(1-(4-morpholinophenyl)-1H-phenanthro[9,10-d]imidazol-2-yl)vinyl)benzenamine and ammonium acetate in acetic acid (120 °C; 12 h; N₂ stream). The formed SMPI-TPA and SMPI-Cz were analysed by various spectroscopic methods, from which their molecular structures were confirmed.

3.1 Potential energy surface (PES) scan studies and thermal properties

The potential energy surface scan of N₂₄–C₂₅–C₃₁–C₃₀ (SMPI-Cz)/N₂₄–C₂₅–C₃₁–C₃₀ (SMPI-TPA) was performed using DFT/B3LYP/6-31G (d,p). During calculation, all the geometrical parameters were simultaneously relaxed, while their respective torsional angles were varied in steps of 0°, 20°, 40°, 60°, 80°, 100°, 120°, 140°, 160°, 180°, 200°, 220°, 240°, 260°, 280°, 300°, 320°, 340°, 360°. The potential energy surface diagrams (Fig. 1a and b) reveal that the minimum energy conformation corresponds to that in which the 4-morpholinophenyl ring attached to the imidazole nitrogen atom (N₂₃) is tilted to an angle of 98.21° (SMPI-Cz)/101.1° (SMPI-TPA) and the phenyl ring with carbazole core (SMPI-Cz) and another phenyl ring with triphenylamine core (SMPI-TPA) are attached to the imidazole carbon atom (C₂₅) at an angle of 91.56° (SMPI-Cz)/110.1° (SMPI-TPA) (Fig. 1c). Owing to rigid molecular back bone and non-coplanar geometry, these compounds (SMPI-TPA and SMPI-Cz) exhibit suitable thermal stability [high decomposition (T_d5)/high glass transition (T_g) temperature: 526/163 °C-SMPI-TPA and 518/172 °C-SMPI-Cz] (Fig. 1d; Table 1). The high T_g and T_d5 values improve the lifetime of the OLEDs by forming thin films upon vacuum evaporation. ²¹
3.2. HOMO–LUMO

The HOMO of both SMPI-TPA and SMPI-Cz is localized on the fragment attached to phenanthrimidazole nitrogen, while the LUMO is distributed on the phenanthrimidazole with TPA (SMPI-TPA) and Cz (SMPI-Cz) fragments (Fig. 2). The HOMO and LUMO of SMPI-TPA and SMPI-Cz display adequate separation in electron density features, which enhances the hole- and electron-transport functions and also reduces the singlet-triplet splitting. Moreover, SMPI-TPA and SMPI-Cz exhibit redox waves, supporting their carrier transport abilities. The HOMO energies of $-5.41$ eV (SMPI-TPA) and $-5.39$ eV (SMPI-Cz) are determined from their respective oxidation onset potentials of $0.61$ V (SMPI-TPA) and $0.59$ V (SMPI-Cz) [$E_{\text{HOMO}} = -[E_{\text{ox}} + 4.8 \text{ eV}]$]. The LUMO energies of $-2.15$ eV (SMPI-TPA) and $-2.17$ eV (SMPI-Cz) are calculated using the equation $E_{\text{LUMO}} = E_{\text{HOMO}} - 1239/\lambda_{\text{onset}}$. The charge-transporting properties of SMPI-TPA and SMPI-Cz were investigated by fabricating single-carrier devices. The hole-only device has the configuration of ITO/NPB (50 nm)/SMPI-TPA or SMPI-Cz (30 nm)/NPB (50 nm)/Al (200 nm) and the electron-only device has the configuration of ITO/TPBI (20 nm) SMPI-TPA or SMPI-Cz (30 nm)/TPBI(20 nm)/LiF (1 nm)/Al (200 nm). NPB on the cathode side of the hole-only device and TPBI (1,3,5-tri(phenyl-2-benzimidazolyl)benzene) on the anode side of the electron-only device were used to block electron injection from Al and hole injection from ITO, respectively. Fig. 3 shows that both devices can significantly conduct current, indicating that SMPI-TPA and SMPI-Cz are capable of transporting both holes and electrons and they exhibit a bipolar transporting nature. This is beneficial for balancing the holes and electrons in the emitting layer based on SMPI-TPA and SMPI-Cz.

3.3. Photophysical properties

Electronic spectral studies of SMPI-TPA and SMPI-Cz were carried out in dichloromethane (Fig. 3). The results indicated that $\lambda_{\text{abs}}$ at around 248 nm originated from the aryl group attached to the nitrogen of phenanthrimidazole plane, while $\lambda_{\text{abs}}$ at around 355 nm was attributed to $\pi \rightarrow \pi^*$ electronic transition of the styryl phenanthrimidazole ring. The origin of absorption of SMPI-TPA and SMPI-Cz was studied by computational methods. The outcomes of computational and experimental methods are similar [HOMO–LUMO+1 transition; Table S1(a) & (b)†]. These SMPI-TPA and SMPI-Cz derivatives show blue emission at 441 and 412 nm, respectively, and the measured PLQY values for SMPI-TPA and SMPI-Cz in solution/film are of 0.81/0.56 and 0.69/0.71, respectively. The emission maximum of SMPI-Cz (412 nm) is blue-shifted when compared with SMPI-TPA (441 nm) due to the additional phenyl ring in SMPI-TPA, which induces an elongated conjugation. Such high fluorescence efficiencies of SMPI-TPA and SMPI-Cz confirmed that they could be efficient deep blue emitters. The calculated triplet energy levels of $2.32$ eV (SMPI-TPA) and $2.40$ eV (SMPI-Cz) are sufficiently high for the excitation of green dopants. The theoretically estimated singlet-to-triplet energy gaps ($\Delta E_{\text{ST}}$) of SMPI-TPA and SMPI-Cz are 0.36 eV and 0.30 eV, respectively, which are unfavourable for TADF emission. A small $\Delta E_{\text{ST}}$ value is required for efficient energy transfer from host T* (triplet excited state) to green phosphorescent emitters. The observed
intense blue emission and high $T_g$ of SMPI-TPA and SMPI-Cz confirmed their suitability as blue emitters. The device performances of the blue emitters were analysed by fabricating non-doped OLEDs with a configuration of ITO/NPB (50 nm)/TCTA (5 nm)/SMPI-TPA (I)/SMPI-Cz (II) (30 nm)/TPBI (15 nm)/LiF (1 nm)/Al (100 nm). It is clear from Fig. 4 and Table 1 that the as-fabricated novel SMPI-TPA- and SMPI-Cz-based blue OLEDs exhibit maximum brightness at low voltage. The blue EL and PL spectra of SMPI-TPA and SMPI-Cz in the solid state are similar (Fig. 3), and the hole injection barrier between SMPI-TPA and HTL (hole transport layer) is very small. Thus, effective electron–hole radiative recombination occurs in SMPI-TPA and SMPI-Cz layers. The small injection barrier of 0.28 (SMPI-TPA) and 0.32 eV (SMPI-Cz) for charge carriers accounts for the observed low turn-on voltages. The SMPI-TPA film exhibits smooth surface (roughness of 0.24 nm) and remains unchanged even after annealing (100 °C; 10 h) (Fig. 4: inset). The value of $\eta_{ex}$ is calculated using the formula $\eta_{ex} = \eta_{out} \times \eta_r \times \eta_v \times \varphi_{pl},$ where $\eta_{out}$ is the light out-coupling efficiency (20%), $\eta_r$ is the product of the charge recombination efficiency (100%), $\eta_v$ is the efficiency of radiative exciton formation (25%) and $\varphi_{pl}$ is the photoluminescence quantum yield of emitters SMPI-TPA (0.56) and SMPI-Cz (0.71). Thus, the calculated $\eta_{ex}$ values of SMPI-TPA- and SMPI-Cz-based devices are 2.8 and 3.6%, respectively. However, the obtained external quantum efficiencies ($\eta_{ex}$) of SMPI-TPA- and SMPI-Cz-based devices are 6.1 and 5.9%, respectively, and the current efficiencies ($\eta_c$) of SMPI-TPA- and SMPI-Cz-based devices are 5.3 and 5.1 cd A$^{-1}$, respectively. The harvested $\eta_{ex}$ exceeds the theoretical limit since delayed fluorescence is not expected and the obtained high $\eta_{ex}$ is not in accordance with TADF.$^{25-30}$ Time-resolved lifetime studies revealed monoexponential decay for SMPI-TPA and SMPI-Cz (Fig. S1†) with lifetime values in nanoscale, indicating the absence of delayed component (TADF) in emission. Both SMPI-TPA and SMPI-Cz do not possess delayed lifetime component. Only prompt species for SMPI-TPA (1.88 ns) and SMPI-Cz (1.92 ns) confirmed that SMPI-TPA and SMPI-Cz are different from TADF materials in luminous mechanism.$^{31}$ The as-fabricated device structure ITO/NPB (50 nm)/TCTA (5 nm)/SMPI-TPA (I) or SMPI-Cz (II) (30 nm)/TPBI (15 nm)/LiF (1 nm)/Al (100 nm) shows that the TCTA layer plays a key role in achieving higher efficiency$^{22}$ and the NPB layer was used as the hole-transporting
layer (HTL) to be deposited in proximity to the SMPI-TPA and SMPI-Cz emissive layers. Due to the relatively small energy gap of NPB ($E_g = 3.00$ eV) in comparison to the energy gaps of the emissive layers SMPI-TPA ($E_g = 3.26$ eV) and SMPI-Cz ($E_g = 3.22$ eV), the excitons generated in the emissive layer are more likely to leak into HTL, leading to loss of excitons. However, herein, we used TCTA with $E_g$ of $3.40$ eV as a buffer layer to confine the excitons within the emissive layer, resulting in higher efficiency. Further, the EL spectra of the SMPI-TPA- and SMPI-Cz-based devices are identical to the corresponding PL emission of the thin film, implying balanced carrier transport and efficient confinement of excitons (Fig. 3). In the present study, some factors account for the efficiency of the devices: (i) bipolar carrier transporting properties of SMPI-TPA and SMPI-Cz, which contribute to better balance of carrier transport and wider distribution of recombination region within the emission layer (Fig. 3) and (ii) suitable HOMO and LUMO energies of SMPI-TPA and SMPI-Cz (Fig. 5); the hole injection barrier at TCTA : EML interface is $0.42$ eV (SMPI-TPA) : $0.44$ eV (SMPI-Cz) and electron injection barrier at TPBI : EML interface is $0.55$ eV (SMPI-TPA) : $0.53$ eV (SMPI-Cz). This reveals that there is only a small barrier for carrier injection, leading to high exciton formation even under high current density, resulting in higher device performances. The PL spectra of SMPI-TPA or SMPI-Cz were recorded in THF/water mixture with different water fractions ($f_w$) to understand whether these materials show aggregation-induced emission. When a small amount of water ($f_w = 10$–$90$ vol%) was added to the THF solution of both SMPI-TPA and SMPI-Cz, the PL intensity remained unchanged, which shows that both SMPI-TPA and SMPI-Cz materials are AIE-inactive (Fig. S1†).

The small singlet–triplet splitting and good carrier transport properties allow both SMPI-TPA and SMPI-Cz to be used as hosts to fabricate red, green and yellow phosphorescence-emitting layers for PhOLEDs. The calculated PLQY of Ir(ppy)$_3$-doped SMPI-TPA and Ir(ppy)$_3$-doped SMPI-Cz was $0.61$ and $0.79$, respectively. In addition to high $h_{ex}$ and $h_{cc},$ SMPI-TPA- and SMPI-Cz-based devices show high $h_p$ (power efficiency) of $5.2$ and $4.6$ lm W$^{-1}$, respectively. The blue emitters exhibit CIE coordinates of (0.16, 0.08) – SMPI-TPA and (0.15, 0.07) – SMPI-Cz. The device based on SMPI-TPA shows maximum luminance of $12 680$ cd m$^{-2}$, and maximum current and power efficiencies of $5.3$ cd A$^{-1}$ and $5.2$ lm W$^{-1}$, respectively, at $3.1$ V. These SMPI-TPA and SMPI-Cz-based devices are thus suitable for fabrication of high performance PhOLEDs.
Ir(ppy)₃ exhibits maximum luminance of 20,725 cd m⁻² (30 nm): 5 wt% Ir(ppy)₃ exhibit maximum luminance of used in the devices are shown in Fig. 5. Devices with SMPI-Cz fabricated device and molecular structures of materials based devices could be attributed to the lower triplet energy of the phosphorescent emitters to reduce the triplet annihilation.

In this study, we have reported the newly fabricated efficient OLEDs both as a blue emitter and as a host for green emission.

4. Conclusion

In this study, we have reported the newly fabricated efficient deep blue-emissive materials with balanced transport and high thermal properties. Non-doped blue emitters with SMPI-TPA and SMPI-Cz exhibits high thermal properties. Non-doped blue emitters with SMPI-Cz are universal hosts for green emitters. The device performance indicates that introduction of a bipolar molecule is a practical strategy for achieving highly efficient OLEDs both as a blue emitter and as a host for green emission.

The device performance indicates that introduction of a bipolar molecule is a practical strategy for achieving efficient OLEDs both as a blue emitter and as a host for green emission.
