Abstract. We perform numerical comparison of the fragmentation mechanism of charmonium production ($gg \to c\bar{c}$ followed by $c \to \psi c$) with the full leading order calculation ($gg \to \psi c\bar{c}$ at $O(\alpha_s^4)$). We conclude that the non-fragmentation contributions remain important up to $J/\psi$ transverse momenta about as large as 40 GeV, thus making questionable the applicability of the fragmentation approximation at smaller transverse momenta.

1 Introduction

The general Factorization principle and the concept of quark and gluon fragmentation functions [1] constitute a widely exploited framework to describe particle production phenomena at collider energies. The method is proved to be mathematically consistent in the region of asymptotically high transverse momenta of the produced particles. The goal of the present consideration is to examine the universality of the quark fragmentation function and to outline the kinematic conditions when the fragmentation approach can be trusted as a reliable approximation.

Our present study was to some extent triggered by the paper [2], where the fragmentation approach was used to describe the experimental data (CDF, ATLAS, CMS) at $p_T > 10$ GeV. To carry out this task, we make a comparison of two calculations. First, we consider an $O(\alpha_s^4)$ calculation for the process $gg \to \psi c\bar{c}$ followed by $c \to \psi c$ and convolute it with an $O(\alpha_s^4)$ fragmentation function $c \to \psi c$, where $\psi$ is meant to be either $J/\psi$ or $\psi(2S)$. Second, we perform a full $O(\alpha_s^4)$ calculation for the process $gg \to \psi c\bar{c}$ and see to what extent does the ‘full result’ matches the fragmentation interpretation.

2 Perturbative color-singlet fragmentation $c \to \psi c\bar{c}$

To calculate the charmed quark fragmentation function, we start with the process $e^+e^- \to \gamma \to \psi c\bar{c}$ considered in the virtual photon rest frame with the $z$ axis oriented along the negative direction of the charmed antiquark momentum. The corresponding Feynman diagrams are displayed in Fig. 1.

![Feynman diagrams](image)

Fig. 1. Feynman diagrams used to calculate the $c \to \psi$ fragmentation function from $e^+e^-$ annihilation, $e^+e^- \to \gamma \to \psi + c + \bar{c}$.

The fully differential cross section then reads

$$
\frac{d^2 \sigma}{d\Omega dp^2} = \frac{1}{2s\pi} \frac{1}{8s} \left| M(ee \to \gamma) \right|^2 \left| M(\gamma \to \psi c\bar{c}) \right|^2 \frac{\lambda^{1/2}(p^2, m_{\psi}^2, m_{c\bar{c}}^2)}{M(\psi c\bar{c})^4} \frac{\lambda^{1/2}(s, p^2, m_{\psi}^2)}{8p^2} \times d\Omega dp^2 d\phi d\cos \theta,
$$

where $s$ is the overall invariant energy; $p_\psi$, $p_1$ and $p_2$ the 4-momenta of $J/\psi$ meson and the charmed quark and antiquark, respectively; $\Omega$, $\phi$, and $\theta$ the angular variables of the reaction; $\lambda$ is the standard ‘triangle’ kinematic function [3]; and the momentum $p = p_1 + p_\psi$ represents the fragmenting (or ‘parent’) quark momentum.

The above formula can be interpreted as a product of the quark production cross section

$$
\frac{d\sigma(e^+e^- \to c\bar{c})}{d\Omega} = \frac{1}{2s} \frac{1}{8s} \frac{\lambda^{1/2}(s, p^2, m_{\psi}^2)}{M(ee \to c\bar{c})^2} \times d\Omega
$$

(2)
and the $c$-quark fragmentation probability. After dividing Eq. (1) by Eq. (2) we arrive at the definition of the differential fragmentation function

$$dD(c^* \rightarrow \psi c) = \frac{1}{(2\pi)^3} \frac{|M(\gamma^* \rightarrow \psi c\bar{c})|^2}{|M(\gamma^* \rightarrow c\bar{c})|^2} \frac{d^3p}{p^2} \frac{d\phi}{2} d\cos \theta. \quad (3)$$

The latter can be further reduced to the conventional fragmentation function $D_{c/\psi}(z)$ by introducing the light-cone variable $z = p_\psi^+/p^+ = (E_\psi + p_{\psi,2})/(E + p_z)$ and integrating over all other variables in Eq. (3):

$$D_{c/\psi}(z) = \int \frac{dD(c^* \rightarrow \psi c) \delta(z - p_\psi^+/p^+)}{d\cos \theta}. \quad (4)$$

Calculations show almost no dependence on $e^+e^-$ energy, what confirms the full dominance of the fragmentation regime. Our results are plotted in Fig. 2 by solid curves. They are fully consistent with other $O(\alpha^2)$ calculations presented in the literature [5,10,17]. Comparison with data would need inclusion of higher order corrections, can be done effectively in terms of radiatinal energy loss [8], however we prefer here to stay with LO order approximation, aiming at the comparison with other LO results.

3 Proton-proton collision

3.1 Glue-glue fusion

In $pp$ collisions the leading order process of $J/\psi\bar{c}c$ production is glue–glue fusion,

$$g + g \rightarrow J/\psi + c + \bar{c}. \quad (5)$$

We employ the Feynman diagrams depicted in Fig. 3 which are all necessary to compose a gauge invariant set (for more details see [4], where one can find explicit algebraic expressions for all of these diagrams).

In fact, we will perform two calculations in parallel, using the ordinary (collinear) and the $k_T$-factorization approaches. The latter can be treated as an effective Next-to-Leading order (NLO) calculation, since a significant part of higher-order radiative corrections is taken into account in the form of $k_T$-dependent (unintegrated) gluon densities.

The evaluation of Feynman diagrams is straightforward and follows the standard QCD rules. For the initial off-shell gluons (if any) We adopt the $k_T$-factorization prescription [9] for the initial off-shell gluons, the spin density matrix is taken in the form $\epsilon_\mu^g \epsilon^\nu_{g'} = k_T^\mu k_T'^\nu / |k_T|^2$, where $k_T$ is the component of the gluon momentum normal to the beam axis. In the collinear limit, when $k_T \rightarrow 0$, this expression converges to the ordinary $\epsilon_\mu^g \epsilon^\nu_{g'} = -g^{\mu\nu}/2$, while in the case of off-shell gluons it contains an admixture of longitudinal polarization. Calculation of the traces and of all Feynman diagrams was done with the algebraic system FORM [10].
To purify the theoretical analysis, we will restrict it to a comparison between the color-singlet [11,12,13] calculations only; that would be sufficient for the goal of the present study. The produced color-singlet $cc$ dipole of a small separation $\sim 1/m_c$, should be projected to the large-size charmonium wave function. Neglecting the small size of the dipole, one arrives at a simple result, the value of the radial wave function at the origin $|R(0)|^2$. While the charmonium wave function with realistic potentials is known, and its convolution with the dipole size distribution would be more accurate [14,15], we rely here on the small-dipole approximation. Then, the $\psi$ production probability contains only one parameter, $|R(0)|^2$, which is known from the charmonium leptonic decay width [16].

Summarizing, the fully differential cross section reads

$$d\sigma(pp \rightarrow \psi ccX) = \frac{\pi \alpha_s^2}{32 s} \left| R(0) \right|^2 \frac{1}{4} \sum_{\text{spins}} \sum_{\text{colors}} |\mathcal{M}(gg \rightarrow \psi cc)|^2 \times F_g(x_1, k_T^2, \mu^2) F_g(x_2, k_T^2, \mu^2) \times dk_T^2 \, dk_{cT}^2 \, dy_\psi \, dy_c \, d\phi_1 \, d\phi_2 \, d\phi_c \, d\phi_\psi,$$

where $s$ is the total initial invariant energy squared, $\hat{s}$ the squared energy of the partonic subprocess, $x_1$ and $x_2$ the parton light-cone momentum fractions, $k_T$, $k_{cT}$, $\phi_1$ and $\phi_2$ the transverse momenta and azimuthal angles of the initial (off-shell) gluons, and $y_\psi$, $y_c$, $y_c$, $p_{cT}$, $p_{cT}$, $p_{cT}$, $p_{cT}$, $\phi_\psi$, $\phi_c$ and $\phi_c$ the rapidities, transverse momenta and azimuthal angles of $\psi$ and the accompanying charmed quark and antiquark, respectively.

Throughout this paper, we use the "A0" parametrization [11,12] for the $k_T$-dependent gluon densities $F_g(x, k_T^2)$ with $\mu^2 = \hat{s}/4$. For collinear calculations we omit the integration over $k_T$ and use the MSTW leading-order set [19] for the ordinary gluon distribution functions. The multidimensional integration in (6) has been performed by means of the Monte-Carlo technique, using the routine VEGAS [20].

### 3.2 Theoretical experiment: "jet" reconstruction

The results of calculation of the full set of graphs should contain a contribution of charm fragmentation. To quantify such a contribution one needs to reconstruct the fragmenting quark momentum. A $\psi$ produced this way should be accompanied with either $c$ or $\bar{c}$, thus referring to the quark or antiquark fragmentation. To search for such correlations one can select the configurations of $\psi$ with lowest two-body invariant mass, either $(M(\psi c) < M(\psi \bar{c}))$, or vice versa. Of course any of such correlations are disturbed by other hadrons produced from the debris of the colliding protons. In the case of collinear factorization the transverse momenta of such hadrons are limited and their influence should fade away at large $p_{cT}$. However, in the case of the approach, based on $k_T$ factorization, the tail $M(\psi c)$ dependence of the gluon distribution, $1/k_T^4$, is close to the $p_T$ dependence of charm production. Therefore, in this case one cannot separate well the contribution of the diagrams in Fig.5 from the hadronic background, even at high $p_{cT}$.

The invariant mass distribution in the class of events with minimal $M(\psi c)$ is shown in Fig.4 with different constraints for the charmonium transverse momentum $p_{cT}$ and momentum $p_T$ of the fragmenting $c$-quark. Calculations were done assuming the collinear factorization scheme. Remarkably, the solid and dashed curves corresponding to equal cuts for $p_{cT}$, are not sensitive to the value of $p_T$. These curves are practically indistinguishable. This observation signals about importance of the fragmentation mechanism. Indeed, in this case the momentum $p_T$ of the fragmenting quark cannot be smaller than $p_{cT}$.

Another method, similar to the jet clustering algorithm, is to select the configuration with the smallest angular separation between $\psi$ and the accompanying $c$ or $\bar{c}$: $R = \sqrt{(\Delta \phi)^2 + (\Delta \eta)^2}$, where $\Delta \phi$ and $\Delta \eta$ are the difference of azimuthal angles and between of pseudo-rapidities for the produced $c$-quark and $\psi$ respectively. This corresponds to the intuitive picture of correlating comoving products of fragmentation, which are usually considered as a signature of a jet.
We separated all theoretically generated events into two classes $R(\psi \bar{c}) < R(\bar{c}\psi)$ and vice versa. Then we checked the $\phi$ and $\eta$ correlations in each of these classes of events. Some examples for such distributions, calculated with the collinear factorization approach, are presented in Figs. 4 and 5 for $\Delta\phi$ and $\Delta\eta$ respectively.

Again, the solid and dashed curves are almost indistinguishable: the requirement that $p_{cT}$ is large means automatically that the sum $p_{\psi T} + p_{cT}$ is also large.

We see that with harder cuts on $p_T$’s the system becomes better collimated (narrower $\Delta\phi$ and $\Delta\eta$ distributions) and so, better suits the fragmentation topology. However, the fact that the shape of these distributions depends on the selected $p_{cT}$ indicates that we are not yet in the fragmentation regime.

Remarkably, both methods lead to rather similar consequences. The quality of our selection rules and the effect of kinematic constraints on $p_\psi$ and $p^*$ are illustrated in Figs. 4 - 6.

As far the products of fragmentation can be identified, we can sum up the momenta of the meson and its closest charmed partner and call it the parent quark momentum, $p^* = p_\psi + p_c$. The fragmentation variable $z$ is then defined in the usual manner: $z = p_\psi^*/p^*$. Then we can extract the effective fragmentation function $D_{c/\psi}(z)$ and compare it with the fragmentation function from $e^+e^-$. The fragmentation mechanism is expected to be important at high transverse momenta, so some kinematic constraints should be imposed. In Fig. 6 we compare the effective fragmentation functions obtained with different kinematic cuts. They disagree with each other and both of them disagree with the fragmentation function derived from $e^+e^-$ annihilation. Nevertheless, with a higher cut $p_{cT} > 50$ GeV, $p_{T}^* > 50$ GeV; dashed curve, $p_{\psi T} > 50$ GeV, $p_{T}^* > 20$ GeV; dotted curve, $p_{\psi T} > 20$ GeV, $p_{T}^* > 50$ GeV; dotted curve, $p_{\psi T} > 20$ GeV, $p_{T}^* > 50$ GeV. For every given cell, one can plot a distribution in $z$ normalizing by the appropriate cross-sec-
tion of quark pair production,

$$D(z) = \frac{d}{dz} \left[ \int d^3 p^* \sigma(gg \rightarrow \psi c \bar{c}) / \left[ \int d^3 p^* \sigma(gg \rightarrow c \bar{c}) \right] \right],$$  \hspace{1cm} (7)

what would give the true quark fragmentation function for a chosen $\Delta t(p^*)$. By definition, the fragmentation function should be independent of the chosen $p^*$ (provided that $p_T^*$ is large enough to fulfill the conditions of the factorization theorem). Then, one can average the statistics over many cells, extending the integration in the above formula up to an arbitrarily large part of the phase space, $p_T^* > p_{T,min}^*$. If the distributions calculated for different choices of $p_{T,min}^*$ do not coincide, one concludes that the assumption on universality of fragmentation function is violated.

The situation in the $k_T$-factorization case is even more complicated. Here we have an extra contribution to the transverse momentum that comes from the primordial $k_T$ of the initial gluons. The large-$k_T$ behavior of the gluon densities is nearly power-like, $F_g(x, k_T^2, \mu^2) \sim 1/k_T^4$, and is comparable with the $p_T$ dependence of the hard scattering matrix element. So, there always presents a non-negligible contribution to the $p_T$ of essentially non-fragmentation nature.

These our observations are confirmed by the results of calculations of the $p_T$ spectra of $J/\psi$ mesons produced in $pp$ collisions at $\sqrt{s} = 7$ TeV, depicted in Fig. 7. The "full LO" and "fragmentation" curves seem to converge at around $p_{\psi T} \simeq 40$ GeV in the collinear case (upper panel), but seem to never come together in the $k_T$-factorization case (lower panel). This figure indicates that making use of the fragmentation approach below 40 GeV is by no means justified. But even at $p_{\psi T} > 40$ GeV the apparent agreement between the curves might be partially a fortune, rather than a consequence of the factorization theorem (recall the disagreement between the $z$ distribution at $p_{\psi T} > 50$ GeV in Fig. 6 and the fragmentation function derived from $e^+e^-$ annihilation).

Going to higher order calculations for the charm fragmentation function would not help, since the origin of the problem is not in the fragmentation function on its own, but rather in the unavoidable presence of large non-fragmentation contributions. Inclusion of the color octet production scheme cannot help either, as it would not solve the problem in the color singlet channel and, most probably, will suffer from the same troubles, in view of much larger number of non-fragmentation diagrams.

4 Conclusions

We compared $J/\psi c \bar{c}$ production in $pp$ collisions, calculated within the collinear factorization scheme with the full LO set of diagrams, and the net fragmentation mechanism with the fragmentation function resulted from $e^+e^-$ annihilation. The non-fragmentation contribution is found to be rather large, extending up to transverse momenta about as high as 40 GeV. These contributions significantly change the slope of the $p_{\psi T}$ spectrum in the intermediate region (between 10 and 40 GeV). The accuracy of the fragmentation approximation cannot be improved with either more precise calculations of the charm fragmentation function, or including the color octet production channels. The presence of essentially non-fragmentation contributions makes the fragmentation approximation below 40 GeV groundless.

We also performed calculations within the approach based on the $k_T$-factorization assumption. In this case the non-fragmentation partial contribution remains important, and even rises at large $p_T$. This happens because of too large primordial gluon momenta $k_T$, which break down the principle of factorizing short and long distances in the process.
