Abstract: A theoretical model of amperometric enzyme electrodes has been developed in which chemical amplification occurs in a single enzyme membrane via cyclic substrate conversion. The system is based on non-stationary diffusion equations with a nonlinear factor related to the Michaelis–Menten kinetics of the enzymatic reaction. By solving the nonlinear equations using the AGM technique, simple analytical expressions of concentration substrate, product, and amperometric current response are derived. Further, biosensor sensitivity, resistance, and gain are obtained from the current. MATLAB programming was used to carry out the digital simulation. The analytical results are validated with the numerical results. The effect of substrate concentration, maximum enzymatic rate, and membrane thickness on biosensor response was evaluated.

Keywords: mathematical modelling; biosensor; amperometry; nonlinear equations; amplification

1. Introduction

Biosensors are two-component devices that consist of a biological entity, typically a redox enzyme that recognises the target analyte, and a transducer that converts the bio-recognition event between the biocatalyst and reactant/substrate (typically a binding/adduct formation process between the active site and substrate) into a measurable signal. Electrochemical or amperometric biosensors measure variations in a current at a working indicator electrode arising from the direct electrochemical oxidation or reduction of the biochemical reaction products [1–9]. Amperometric biosensors typically operate in a batch mode under conditions of constant applied electrode potential with concomitant monitoring of the steady-state current response arising from an electron transfer reaction at the sensor/electrode interface. This current is directly related to the concentration of the analyte. Amperometric biosensors are safe, inexpensive, and environmentally friendly, and, consequently, have found significant clinical and industrial applications.

It is very important to be able to quantitatively describe reaction and diffusion within bounded surface regions of the type encountered in amperometric biosensor systems. Typically, such systems may be very complex, and the challenge is to develop the simplest mathematical model that enables the description of the steady-state or transient current as a function of the substrate concentration. Typically, the mathematical model involves proposing a geometry-dependent reaction/diffusion equation subject to well-defined initial and boundary conditions for the substrate concentration within the bounded biosensing layer, which reflect the experimental conditions relevant to the sensing process. Typically, it is assumed that substrate transport is described by Fick’s law of diffusion and the reaction kinetics quantified in the first instance by the Michaelis–Menten rate equation. This is usually a good choice since Michaelis–Menten kinetics describe a binding event or adduct
formation process that typifies the interaction between an immobilized enzymatic active site and a substrate molecule. Hence, using this approach, an approximate analytical solution to the boundary value problem describing the biosensor operation can be developed, which will describe the steady state or transient concentration profiles of reactant and product through the bound catalytic layer as a function of distance and time. It also enables an expression for the net reaction rate or flux expressed as a current to be derived. This can be related in a definite manner to real system parameters such as catalyst loading, catalyst concentration, substrate concentration, and layer thickness. The mathematical model should make simple predictions on how the reaction rate depends on each of the latter parameters and thereby enable the rational design of a modified electrode sensor in which substrate detection/catalysis is optimized.

The sensitivity of an amperometric sensor is a useful parameter and determines the detection limit of the device. Recently, Rajendran and et al. derived analytical expressions for the current, sensitivity, and resistance of an amperometric biosensor operating where substrate inhibition [10], product inhibition [11], and uncompetitive inhibition processes [12] pertain. Furthermore, Joy Salomi et al. [13] have described the theoretical study of biosensor devices acting in a trigger mode. Analytical steady-state expressions describing the substrate and product concentrations within a bound enzyme thin film on an electrode surface for both non-Michaelis–Menten kinetics [14] and Michaelis–Menten kinetics [15] in an amperometric biosensor have also been derived by solving the pertinent nonlinear reaction/diffusion equations. The theoretical analysis for various types of complex biosensor systems has also been discussed [16–18].

The cyclic conversion of the substrate can enhance the sensitivity of the amperometric enzyme electrodes [19–21]. A membrane containing two enzymes is commonly used to execute the cyclic conversion of the substrate and analyte regeneration. The steady-state response of enzyme electrodes with cyclic substrates conversion was computed when first-order substrate kinetics pertain [19]. By solving diffusion equations and employing Green’s functions, the dynamic behaviour of these electrodes was investigated [22]. Other amperometric electrodes have been developed by utilising cyclic substrate conversion in single enzyme membranes [22]. In these electrodes, cyclic conversion of the substrate was carried out by conjugating the enzymatic reaction with the chemical or electrochemical process. The digital simulation of the biosensor response was carried out using the implicit finite difference scheme by various researchers [23–25].

This study aims to develop a simple theoretical model that allows the simulation of enzymatic biosensor responses using amplification through coupled electrochemical and enzymatic substrate conversion. The model created is based on non-stationary diffusion equations with a nonlinear factor related to the enzymatic reaction. These equations are analytically solved using the AGM technique. The MATLAB programme was used to perform the digital simulation of the biosensor responses, and this is used to check the accuracy of the analytical solution. The developed theoretical model was employed to investigate the influence of the substrate concentration and the maximal enzymatic rate, as well as the membrane thickness on the biosensor response, sensitivity, resistance, and amplification.

2. Mathematical Formulation of the Problem

The biosensor may be considered as an enzyme electrode consisting of a thin film membrane of thickness $d$ containing an immobilised enzyme applied onto the surface of the electrochemical transducer. Consider the very simple scheme of a substrate $S$ electrochemically converted to a product $P$ at the surface of the support electrode. This product is then enzymatically transformed back to substrate $S$ using an enzyme catalyst $E$. This is perhaps the most simple scheme for substrate cyclic conversion.

$$S \rightarrow P \xrightarrow{E} S$$ (1)
In the case of phenol-sensitive biosensors, for example, 1,2-benzoquinone \((S)\) is reduced electrochemically and the product pyrocatechol \((P)\) formed is then subsequently oxidised in the membrane using immobilised laccase as the enzyme catalyst \((E)\). Coupling of the enzyme-catalysed reaction in the enzyme layer with planar diffusion, described by Fick’s law, leads to the following steady-state reaction/diffusion equations [26]:

For \(0 < x < d\),

\[
D_S \frac{d^2 S(x)}{dx^2} + \frac{V_{\text{max}} P(x)}{K_M + P(x)} = 0 \quad (2)
\]

\[
D_P \frac{d^2 P(x)}{dx^2} - \frac{V_{\text{max}} P(x)}{K_M + P(x)} = 0 \quad (3)
\]

where \(x\) stand for the distance coordinate and \(S(x)\) and \(P(x)\) denote the concentration functions of the substrate and reaction product, respectively. Note that \(V_{\text{max}}\) is the maximal enzymatic rate attainable with that amount of enzyme when the enzyme is fully saturated with substrate. This is given by \(V_{\text{max}} = k_{\text{cat}} e \Sigma\), where \(k_{\text{cat}}\) denotes the catalytic rate constant and \(e \Sigma\) denotes the total enzyme concentration in the layer. Note that \(K_M\) denotes the Michaelis constant, \(d\) the thickness of the enzyme layer, and \(D_S\) and \(D_P\) the diffusion coefficients of the substrate and product, respectively. Let \(x = 0\) represent the electrode surface, while \(x = d\) represents the bulk solution/membrane interface. The operation of the biosensor begins when some substrate appears over the surface of the enzyme layer.

The electrode potential is chosen to ensure complete transformation of substrate to product at the electrode so that the substrate concentration at the electrode surface is zero. During electrochemical conversion, the product is produced. The rate of the product generation at the electrode is proportional to the rate of conversion of the substrate. When the solution is well-stirred outside the membrane, the diffusion layer \((0 < x < d)\) remains at a constant thickness. Consequently, the concentration of substrate, as well as product, over the enzyme surface (bulk solution/membrane interface) remains constant while the biosensor contacts the substrate solution. This is reflected in the boundary conditions given by:

\[
S(x = 0) = 0 \quad (4)
\]

\[
S(x = d) = S_0 \quad (5)
\]

\[
D_S \left. \frac{dS}{dx} \right|_{x=0} + D_P \left. \frac{dP}{dx} \right|_{x=0} = 0 \quad (6)
\]

\[
P(x = d) = 0 \quad (7)
\]

where \(S_0\) is the concentration of substrate in the bulk solution. Note that we have neglected concentration polarization in the solution phase adjacent to the immobilized enzyme layer. This can, of course, be readily accounted for in the analysis.

The current is measured at the support electrode/enzyme layer interface and defines the response of the biosensor device to the chemical activity in the enzyme layer. The current depends upon the flux of the substrate \(S\) at the electrode surface, i.e., at \(x = 0\). Consequently, the current density \(i\) can be obtained explicitly from Faraday’s law and Fick’s law via:

\[
i = n_e F D_S \left. \frac{dS(x)}{dx} \right|_{x=0} = -n_e F D_P \left. \frac{dP(x)}{dx} \right|_{x=0} \quad (8)
\]

where \(n_e\) is a number of electrons involved in a charge transfer at the electrode surface and \(F\) is Faraday constant \(F \approx 9.65 \times 10^4 \, \text{C/mol}\).

**Dimensionless Form of Problem**

To facilitate further analysis, it is often useful to cast the reaction/diffusion problem into dimensionless form. We can make the reasonable assumption that \(D_S = D_P = D\). The
A dimensionless steady-state model of the system under consideration can be obtained from Equations (2) and (3) and is given as follows:

\[
\frac{d^2 u(X)}{dX^2} + \frac{\sigma^2 v(X)}{1 + \alpha v(X)} = 0 \quad (9)
\]

\[
\frac{d^2 v(X)}{dX^2} - \frac{\sigma^2 v(X)}{1 + \alpha v(X)} = 0 \quad (10)
\]

where the dimensionless variables are given by

\[
u = \frac{S}{S_0}, \quad v = \frac{P}{S_0}, \quad X = \frac{x}{d}, \quad \sigma^2 = \frac{V_{\text{max}} d^2}{D K_M}, \quad \alpha = \frac{S_0}{K_M} \quad (11)
\]

The boundary conditions are transformed as follows:

At \(X = 0\) : \(u(X) = 0, \frac{du(X)}{dX} + \frac{dv(X)}{dX} = 0 \quad (12)\)

At \(X = 1\) : \(u(X) = 1, v(X) = 0 \quad (13)\)

The current density in dimensionless form is \([17]\)

\[
\psi = \frac{i}{n_e F D S_0} \left[ \frac{d}{dX} \right] = \left. \frac{du(X)}{dX} \right|_{X=0} = - \left. \frac{dv(X)}{dX} \right|_{X=0} \quad (14)
\]

The steady-state current \(I\) of the biosensor is expressed as follows:

\[
I = - \left. \frac{n_e F D S_0}{d} \frac{dv(X)}{dX} \right|_{X=0} \quad (15)
\]

We note that the reaction/diffusion expressions presented in Equations (9) and (10) are nonlinear. Previously, such nonlinear equations were solved in the limit of low and high substrate concentrations. In this work we will proceed to use a recently established protocol to derive a useful analytical solution to these expressions which is valid over a wide region of substrate concentration.

3. An Approximate Analytical Expression of Steady-State Concentrations Using AGM

Recently, some nonlinear differential equations have been solved using several analytical or semi-analytical methods, even with strong nonlinearities. Of these methods, we mention the homotopy analysis method \([27]\), the Adomian decomposition method \([28]\), the variational iteration method \([29]\), and the Green’s function iterative method \([30,31]\). Recently, the homotopy perturbation method (HPM) \([32–34]\), the Akbari-Ganji method (AGM) \([35–37]\), and the Taylor series method \([38–41]\) have proven to be particularly useful and, therefore, have received a great deal of attention.

The approximate analytical expression for the dimensionless stationary concentration of substrate \(u\) and product \(v\) is obtained as follows (Appendix A):

\[
u(X) = 1 - \cosh(\sqrt{\gamma} X) + \sinh(\sqrt{\gamma} X) \coth(\sqrt{\gamma}) \quad (16)
\]

\[
v(X) = \cosh(\sqrt{\gamma} X) - \sinh(\sqrt{\gamma} X) \coth(\sqrt{\gamma}) \quad (17)
\]

where we note that:

\[
\gamma = \frac{\sigma^2}{1 + \alpha} \quad (18)
\]

We can also show that the normalised current becomes:

\[
\psi = \sqrt{\gamma} \coth(\sqrt{\gamma}) \quad (19)
\]
The steady-state current $I$ is given by

$$I = \frac{n_e F D S_0}{d} \sqrt{\gamma} \coth(\sqrt{\gamma})$$

(20)

This general expression for the steady-state current response is valid over a wide range of substrate concentrations. We now examine some interesting limiting cases corresponding to the situation where the concentration of substrate is much less than the Michaelis constant and when it is much greater.

3.1. Limiting Case: Unsaturated (First-Order) Catalytic Kinetics

We first consider the situation where the substrate concentration level in the enzyme layer is less than the Michaelis constant $K_M$, ($S_0 \ll K_M$). This situation will pertain when $a \nu \ll 1$. In such circumstances, Equations (8) and (9) reduce to the linear reaction–diffusion equations:

$$\frac{d^2 u(X)}{dX^2} + \sigma^2 v(X) = 0$$

(21)

$$\frac{d^2 v(X)}{dX^2} - \sigma^2 v(X) = 0$$

(22)

By solving Equations (21) and (22) with their corresponding boundary conditions (Equations (12) and (13)), the exact expression of the concentrations of substrate $u$ and product $v$ and current has been obtained as follows:

$$u(X) = 1 - \cosh(\sigma X) + \coth(\sigma) \sinh(\sigma X)$$

(23)

and

$$v(X) = \cosh(\sigma X) - \coth(\sigma) \sinh(\sigma X)$$

(24)

The steady-state current $I$ is

$$I = \frac{n_e F D S_0}{d} \sigma \coth(\sigma)$$

(25)

This expression is valid for all values of the parameter $\sigma$.

3.2. Limiting Case: Saturated (Zero-Order) Catalytic Kinetics

We now examine the situation where the substrate concentration level in the enzyme layer is greater than the Michaelis constant $K_M$, ($S_0 >> K_M$). This situation will pertain when $a \nu \gg 1$. Here, Equations (9) and (10) reduce to the linear reaction–diffusion equations:

$$\frac{d^2 u(X)}{dX^2} + \frac{\sigma^2}{\alpha} = 0$$

(26)

$$\frac{d^2 v(X)}{dX^2} - \frac{\sigma^2}{\alpha} = 0$$

(27)

By solving Equations (26) and (27) with their corresponding boundary conditions (Equations (12) and (13)), the exact expression of the concentrations of substrate $u$ and product $v$ and current has been obtained as follows:

$$u(X) = \left(1 + \frac{\sigma^2}{2\alpha}\right) X - \frac{\sigma^2}{2\alpha} X^2$$

(28)

and

$$v(X) = 1 - \left(1 + \frac{\sigma^2}{2\alpha}\right) X + \frac{\sigma^2}{2\alpha} X^2$$

(29)
The steady-state current $I$ is

$$I = \frac{n_e F D S_0}{d} \left( 1 + \frac{\alpha^2}{2\kappa} \right) = \frac{n_e F D S_0}{d} + \frac{n_e F d \kappa e \Sigma d}{2}$$

(30)

We note that the latter expression contains two terms. The first corresponds to the diffusion of substrate through the matrix. The second corresponds to the decomposition of the product/enzyme complex to regenerate the substrate. The factor of 2 arises from the fact that the product generated at the electrode may also be lost by diffusion through the enzyme layer, as well as reacting at the enzyme to generate substrate $S$. Here, the product concentration is much larger than the Michaelis constant of the enzyme ($p/K_M \gg 1$).

4. Validation of Analytical Results

In this section, we present numerical simulations to test the accuracy and reliability of the proposed method. The analytical expressions obtained in this paper have been compared with the highly accurate numerical solution obtained by the MATLAB routine bvp4c, which is a finite-difference code that implements the three-stage Lobatto IIIA formula. The analytically derived (Equations (16) and (17)) and computationally simulated concentration profiles of substrate and product within the enzyme layer are compared in Figure 1. These curves were computed for the following typical parameter values: $K_M = 10^{-7}$ mol cm$^{-3}$, $S_0 = 10^{-7}$ mol cm$^{-3}$, $D = 3 \times 10^{-6}$ cm$^2$ s$^{-1}$, $d = 0.02$ cm, and $V_{\text{max}} = 10^{-7}$ mol cm$^{-2}$ s$^{-1}$. The analytical and numerical solutions were plotted on the same coordinates for a wide range of possible values of the underlined problem parameters. It is clear from Table 1 that the fit between the analytical solution to the reaction/diffusion problem in the form of reactant and product concentration profiles, and the corresponding quantity numerically evaluated using MATLAB, is excellent, with average deviation between numerical and analytical results being typically 0.36% for substrate and 0.02% for product.

![Figure 1](image_url)
Table 1. Comparison of dimensionless concentration of the substrate $S$ and product $P$ with simulation results for the parameter values $D = 3 \times 10^{-6}$ cm$^2$ s$^{-1}$, $V_{\text{max}} = 10^{-8}$ mol cm$^{-3}$ s$^{-1}$, $K_M = 10^{-7}$ mol cm$^{-3}$, $S_0 = 10^{-8}$ mol cm$^{-3}$, and $d = 0.02$ cm.

5. Results and Discussion

We note that the solution of the nonlinear reaction/diffusion equations as expressed in Equations (16) and (17) represents new and simple analytical expressions for the concentration substrate and product, respectively. Furthermore, the amperometric current response is described by Equation (20) for all parameter values.

5.1. Influence of Parameter on Concentration of Substrate and Product

The dimensionless concentration profiles of substrate $u$ and product $v$ involved in the cyclic substrate conversion following Michaelis–Menten kinetics are depicted in Figure 1. The experimental values of the parameters used in this figure are $K_M = 10^{-7}$ mol cm$^{-3}$, $S_0 = 10^{-7}$ mol cm$^{-3}$, $D = 3 \times 10^{-6}$ cm$^2$ s$^{-1}$, $d = 0.02$ cm, and $V_{\text{max}} = 10^{-7}$ mol cm$^{-2}$ s$^{-1}$ [26]. From the figure, it can be noted that our obtained analytical result matches quite well with the numerical experiments. Peculiarities of the biosensor activity have been examined using our analytical result for various values of the parameters. The nonlinear distribution of concentration of both compounds throughout the membrane can be observed, and it is noted that the substrate concentration $u$ decreases and the product concentration $v$ increases significantly with decrease of dimensionless distance $X$ from the outer edge of the membrane to the inner electrode/film interface.

5.2. Influence of Transport and Reaction Parameters on the Current Response

In Figure 2a,b the dependence of the maximal biosensor current $\psi$ on the substrate concentration $S_0$ for various values of diffusion coefficient $D$ and the thickness of the enzyme layer $d$ is outlined. We note that the steady-state current response is a monotonously decreasing function of $S_0$ for all values of $D$ and $d$. From Figure 3, it is noted that the biosensor current rises as $V_{\text{max}}$ increases and $K_M$ decreases. Further, it can be deduced that $S_0 > 1$ mol cm$^{-3}$ and the biosensor current is independent of the bulk substrate concentration $S_0$. This is to be expected since, under these conditions, the enzyme sites in the matrix are saturated with substrate.
5.3. Sensitivity of Biosensor

The term sensitivity refers to the change of the biosensor response with regard to a change in the substrate concentration. Since both the current and the substrate concentration vary in order of magnitude, dimensionless sensitivity is another valuable parameter to be considered. The mathematical representation of the non-dimensional biosensor sensitivity for substrate concentration $S_0$ can be estimated from the following [42]:

$$B_s(S_0) = \frac{\partial I(S_0)}{\partial S_0} \times \frac{S_0}{I(S_0)}$$  \hspace{1cm} (31)
where $B_s$ is biosensor sensitivity and $I(S_0)$ is steady-state current density measured at the substrate concentration $S_0$. Therefore, from Equation (20), we can readily show that:

$$B_s(S_0) = \frac{\alpha}{(\alpha + 1)} \left[ \frac{1}{2} - \frac{\sqrt{\gamma}}{\sinh(2\sqrt{\gamma})} \right]$$

(32)

where $\alpha, \gamma$ are defined in Equations (11) and (18). As the maximal enzymatic rate drops down, i.e., $V_{\text{max}} \to 0$, it can be observed that $B_s$ also tends to zero. Quick diffusivity contributes to relatively low sensitivity. Figure 3a supports this inference. When the membrane thickness and enzymatic rate vary by two orders of magnitude, a similar effect is again observed. This shows that thickness of the membrane plays a crucial role in determining the biosensor sensitivity and Figure 3b confirms the same. It is possible to observe from the smooth curves of Figure 3a,b that $0 \leq B_s \leq 0.5$ for all values of the parameters. This assertion receives further confirmation in the 3D plot as outlined in Figure 3c.

5.4. Resistance of Biosensor

The normalised resistance $B_R$ is represented as the gradient of steady-state biosensor current concerning the thickness of membrane $d$ [42]:

$$B_R(d) = \frac{dI(d)}{dd} \times \frac{d}{I(d)}$$

(33)

where $I$ is the steady-state current density measured at membrane thickness $d$. From Equation (32) we obtain

$$B_R(d) = 1 - \frac{2\sqrt{\gamma}}{\sinh(2\sqrt{\gamma})}$$

(34)

From the Equations (32) and (33), the new relationship between sensitivity and resistance can be shown as $B_s(S_0) = \frac{\alpha}{2(\alpha + 1)} B_R(d)$. Hence, there is almost zero resistance for negligibly small values of $V_{\text{max}}$. This can also be observed in the three-dimensional representation of $B_R$ as a function of transport and enzyme kinetics, as presented in Figure 4c. Moreover, from the latter curve we note that the biosensor resistance increases as the diffusion coefficient decreases. The range of biosensor resistance as depicted by the nonlinear curves of Figure 4a,b lies within the bounds from 0 to 1 for all values of the parameters. Both $K_M$ and $S_0$ have a similar effect in the sense that, for their lower values, the device resistance increases.

5.5. Gain of the Biosensor

Sensitivity gain is described as the ratio of the trigger biosensor’s steady-state current ($I_{\text{CEC}}$) to the corresponding CE biosensor’s steady-state current ($I_{\text{CE}}$). This is used to compare the amplified and non-amplified biosensor response. Now, if the enzyme is absent and substrate recycling is absent, then the applied potential dictates that the device is operating under mass transport control, a steady-state limiting current is observed, and the normalised current density is given by $\psi = \psi_L = 1$. Then, the amplification, or gain factor $G$, can be defined by:

$$G(V_{\text{max}}) = \frac{I(V_{\text{max}})}{I(V_{\text{max}} = 0)} = \sqrt{\gamma} \coth(\sqrt{\gamma})$$

(35)

We note that the gain factor $\psi/\psi_L = \sqrt{\gamma} \coth(\sqrt{\gamma})$ depends on the Michaelis–Menten parameters associated with the enzyme catalysis $P \to S$ reaction. When $\sqrt{\gamma} \ll 1$, we note that $\coth(\sqrt{\gamma}) \cong \frac{1}{\sqrt{\gamma}} \left(1 + \frac{\gamma}{3}\right)$, and so the gain factor is given by:

$$G \cong 1 + \frac{\gamma}{3}$$

(36)
In contrast, when $\sqrt{\gamma} \gg 1$, then $\coth(\sqrt{\gamma}) \approx 1$ and the gain factor is given by:

$$G \approx \sqrt{\gamma}$$  \hspace{1cm} (37)$$

These expressions are valid for all values of the saturation parameter $\alpha$.

Figure 5 displays the dependence of the gain $G$ of the steady-state current on the substrate concentration $S_0$ for thinner biosensor film thicknesses $d$. The gain increases up to 27 times approximately at $S_0 > 1$ mol cm$^{-3}$ and $V_{max} = 10^{-3}$ mol cm$^{-3}$ s$^{-1}$. For $V_{max} \leq 10^{-6}$ mol cm$^{-3}$ s$^{-1}$, the gain is less than 4 and is linear, whereas for $K_M \leq 10^{-3}$ mol cm$^{-3}$, the gain is the linear function of $S_0$.

![Figure 3](image_url)
We note that the efficiency factor takes the following form:

\[ \eta = \frac{1 + \Phi/2}{1 + \Phi} f_S = \eta f_S \]  \tag{38} \]

Here, we have introduced an efficiency factor \( \eta \) which determines how much substrate regenerated by the enzymatic reaction of \( P \) is lost to the solution and which cannot take place in amplification. We note that the efficiency factor takes the following form:

\[ \eta = \frac{1 + \Phi/2}{1 + \Phi} \]  \tag{39} \]
while the outer region of the film remains saturated. A moving normalized distance 
where the level of saturation varies across the thickness of the enzyme film [44]. The 
As the substrate \( P \) varies with the kinetic parameter \( \gamma \), biosensor operation can be successfully used to investigate and predict the dynamics of 
the electrochemical reaction at the electrode surface, and hence in signal amplification. 

6. Analysis of ‘Mixed Case’ Moving Boundary Scenario Corresponding to Varying 
Levels of Saturation across the Enzyme Membrane

We have examined the limiting situations for totally saturated kinetics when \( av \gg 1 \) 
and unsaturated kinetics when \( av \ll 1 \). We can also envisage the more complex situation 
where the level of saturation varies across the thickness of the enzyme film [44]. The 
simplest strategy involves the assumption that the inner part of the film is unsaturated, 
while the outer region of the film remains saturated. A moving normalized distance 
parameter \( X^* \) located between the two regions under consideration can be introduced. 
As the substrate \( P \) diffuses into the film, a reaction front will have been established at 
\( X = X^* \). When \( X^* = 1 \), the entire region is unsaturated, while at \( X^* = 0 \), the entire region 
is saturated. Now, at \( X = X^* \), \( v = \frac{1}{\alpha} \). Hence, Equation (17) becomes

\[
\frac{1}{\alpha} = \cosh(\sqrt{\gamma}X^*) - \sinh(\sqrt{\gamma}X^*)\coth(\sqrt{\gamma})
\]

On solving the above Equation (40), \( X^* \) can be obtained as follows:

\[
X^* = \frac{1}{\sqrt{\gamma}} \left[ \ln \left( -\frac{1}{2\alpha} \left( \exp(\sqrt{\gamma})^2 - 1 - \sqrt{\left( \exp(\sqrt{\gamma})^2 - 1 \right)^2 + 4\alpha^2\exp(\sqrt{\gamma})^2} \right) \right) \right]
\]

This expression indicates the manner in which the location of the moving boundary 
varies with the kinetic parameter \( \gamma \) and the saturation parameter \( \alpha \).

7. Conclusions

In this paper, we have shown that a simple mathematical model of an amperometric 
biosensor operation can be successfully used to investigate and predict the dynamics of 
the response of the device when a cyclic substrate conversion operates. New and simple 
approximate analytical expressions of substrate and product concentrations, steady-state 
current, sensitivity, and biosensor resistance are reported. The effect of various physical 
parameters, such as membrane thickness, Michaelis constant, and maximum catalytic rate
on the latter key performance indicators, is also discussed. This theoretical result can be applied in designing novel, highly sensitive biosensors, which minimise enzyme volume without losing sensitivity.

**Appendix A**

For an approximate analytical solution at steady state using AGM, consider Equations (9) and (10) in the main text:

\[
\frac{d^2 u(X)}{dx^2} + \frac{\sigma^2 \psi(X)}{1 + \alpha v(X)} = 0 \tag{A1}
\]
\[
\frac{d^2 v(X)}{dX^2} - \frac{\sigma^2 v(X)}{1 + \alpha v(X)} = 0 \quad (A2)
\]

The corresponding boundary conditions are as follows:

at \( X = 0 \): \( u(X) = 0, \frac{du(X)}{dX} + \frac{dv(X)}{dX} = 0 \) \quad (A3)

at \( X = 1 \): \( u(X) = 1, v(X) = 0 \) \quad (A4)

The approximate analytical solution for the Equation (A2) has been taken as follows:

\[ v(x) = A_1 \cosh(nx) + B_1 \sinh(nx) \quad (A5) \]

Let us take \( v(0) = v_0 \) \quad (A6)

Using the boundary conditions \( v(0) = v_0 \) and \( v(1) = 0 \), the values of the parameters \( A_1, B_1 \) have been obtained as follows:

\[ A_1 = v_0, \quad B_1 = -\frac{v_0 \cosh(n)}{\sinh(n)} \quad (A7) \]

Then Equation (A5) becomes:

\[ v(x) = v_0 \cosh(nx) - v_0 \coth(n) \sinh(nx) \quad (A8) \]

Substituting Equation (A8) in Equation (A1), we get:

\[
A_1 n^2 \cosh(nx) + B_1 n^2 \sinh(nx) - \frac{\sigma^2 (A_1 \cosh(nx) + B_1 \sinh(nx))}{\alpha (A_1 \cosh(nx) + B_1 \sinh(nx)) + 1} = 0 \quad (A9)
\]

Now, substituting \( x = 0 \) in Equation (A9) and on solving the equation, we get:

\[ n = \sqrt{\frac{\sigma^2}{\alpha v_0 + 1}} \quad (A10) \]

Adding Equations (A1) and (A2), we get:

\[ \frac{\partial^2 [u(x) + v(x)]}{\partial x^2} = 0 \quad (A11) \]

The boundary condition becomes:

at \( x = 0 \), \( \frac{d[u(x) + v(x)]}{dX} = 0 \) \quad (A12)

at \( x = 1 \), \( u(x) + v(x) = 1 \) \quad (A13)

Let \( u(x) + v(x) = f(x) \).

Hence, Equation (A11) becomes:

\[ \frac{\partial^2 f(x)}{\partial x^2} = 0 \quad (A14) \]

with the boundary conditions:

at \( x = 0 \), \( \frac{df(x)}{dX} = 1 \), and at \( x = 1 \), \( f(x) = 1 \) \quad (A15)
On solving Equations (A14) and (A15), we get:

\[ f(x) = 1 \]  \hspace{1cm} (A16)

Hence, \( u(x) = 1 - v(x) \)  \hspace{1cm} (A17)

Using Equation (A8) in Equation (A17), we get:

\[ u(x) = 1 - v_0 \cosh(nx) + v_0 \coth(n) \sinh(nx) \]  \hspace{1cm} (A18)

Using the boundary condition \( u(0) = 0 \) in Equation (A18), we get \( v_0 = 1 \).

Hence, \( u(x) = 1 - \cosh(\sqrt{\gamma}x) + \coth(\sqrt{\gamma}) \sinh(\sqrt{\gamma}x) \)  \hspace{1cm} (A19)

\( v(X) = \cosh(\sqrt{\gamma}X) - \sinh(\sqrt{\gamma}X) \coth(\sqrt{\gamma}) \)  \hspace{1cm} (A20)

where the kinetic parameter \( \gamma \) is given by

\[ \gamma = \frac{\sigma^2}{1 + \alpha} \]  \hspace{1cm} (A21)

We recall that \( \sigma^2 = \frac{k_{cat}d}{k_{cat}(D/d)} \) compares the rate of enzyme kinetics with that of the diffusion of P to the enzyme after the reaction via electrochemical reaction at the support electrode surface. In this enzymatic reaction, the substrate S is recycled again and can repeat the cycle, thus generating amplification.

### Appendix B

The relationship between the observed flux \( f_{\text{obs}} \) is measured as a steady-state amperometric current and the enzymatically catalyzed substrate regeneration flux \( f_S \).

In this appendix, we present a discussion which we initially developed some time ago. We consider an electrode surface coated with a thin membrane of thickness \( d \) containing an immobilized enzyme, which is in contact with an aqueous solution containing substrate or reactant species \( S \) at a bulk concentration \( S_0 \). In this appendix, we derive a relationship between the observed flux \( f_{\text{obs}} \), which measures the electrochemical transformation of substrate \( S \) to product \( P \), which can then react catalytically with the enzyme \( E \) to regenerate substrate \( S \). These fluxes are related via the following expression:

\[ f_{\text{obs}} = \eta f_S \]  \hspace{1cm} (A22)

We propose that the substrate \( S \) produced by the enzyme/product reaction is formed at a uniform rate given by \( f_S / d \). Furthermore, some \( S \) will diffuse through the enzyme membrane towards the outer edge of the enzyme membrane layer and into the solution phase. This is described by the Fick diffusion equation. At the steady state, these fluxes balance and we write:

\[ D_S \frac{d^2 S}{dx^2} + \frac{f_S}{d} = 0 \]  \hspace{1cm} (A23)

This equation is solved subject to the following boundary conditions:

\[ x = 0, \quad S = S_0, \quad \frac{dS}{dx} = \frac{f_{\text{obs}}}{D_S} \]  \hspace{1cm} (A24)

\[ x = d, \quad S = S_d \]  \hspace{1cm} (A25)

Note that the boundary condition at \( x = 0 \) corresponds to the situation at the support electrode/enzyme layer interface. The first statement in Equation (A24) is that the potential of the electrode is set to a value such that the reactant species is set to a value such that it is immediately oxidized or reduced at the electrode surface, and so its surface concentration is zero. The second statement refers to the fact that the observed flux arises from the oxidation
of the reactant S at the support electrode surface. The second boundary condition presented in Equation (A25) refers to the interface between the enzyme membrane and the adjacent solution phase at \( x = d \). Here, the substrate concentration has a value \( S_d \).

We can integrate Equation (A23) between 0 and \( d \) to obtain:

\[
D_S \left\{ \left( \frac{dS}{dx} \right)_d - \left( \frac{dS}{dx} \right)_0 \right\} = -f_S \tag{A26}
\]

Now, the observed flux is given by:

\[
f_{obs} = D_S \left( \frac{dS}{dx} \right)_0 \tag{A27}
\]

Then, we can state that:

\[
D_S \left( \frac{dS}{dx} \right)_d = -f_S + f_{obs} \tag{A28}
\]

The flux of S across the enzyme layer/solution interface is now equated with the flux of S across the Nernst diffusion layer in solution which has a thickness \( \delta \), and so we can write:

\[
D_S \left( \frac{dS}{dx} \right)_d = -f_S + f_{obs} = -\frac{D'_S S^* d}{\delta} \tag{A29}
\]

Here, \( D'_S \) denotes the substrate diffusion coefficient in solution and \( S^* d \) represents the substrate concentration in the solution phase just outside the enzyme layer and is related to the substrate concentration at \( x = d \) by \( S_d = \kappa_S S^* d \), where \( \kappa_S \) denotes the partition coefficient of S.

An indefinite integration of Equation (A23) over \([0, x]\) results in:

\[
\frac{dS}{dx} = \frac{f_{obs}}{D_S} - \frac{f_S}{D_S d} x \tag{A30}
\]

A second integration of Equation (A30) results in:

\[
S(x) = S_0 + \frac{f_{obs}}{D_S} x - \frac{f_S}{2D_S d} x^2 \tag{A31}
\]

Noting that \( S_0 = 0 \), and when \( x = d, S = S_d \), we obtain:

\[
S_d = \frac{d}{D_S} \left\{ \frac{f_{obs}}{D_S} - \frac{f_S}{2} \right\} \tag{A32}
\]

From Equation (A29) we can show that:

\[
\frac{D'_S S_d}{\kappa_S d} = f_S - f_{obs} \tag{A33}
\]

Substituting Equation (A32) into Equation (A33), we get:

\[
\frac{D'_S}{\delta} \frac{d}{\kappa_S D_S} \left\{ \frac{f_{obs}}{D_S} - \frac{f_S}{2} \right\} = f_S - f_{obs} \tag{A34}
\]

We now introduce a flux ratio \( \Phi \) given by:

\[
\Phi = \frac{f'^*_{DS}}{f_{DS}} = \frac{D'_S}{\delta} \frac{d}{\kappa_S D_S} \tag{A35}
\]
This quantity relates the diffusive flux of substrate in the diffusion layer to the corresponding diffusion flux of substrate within the enzyme layer. Hence, Equation (A34) transforms to:

$$\Phi \left\{ f_{\text{obs}} - \frac{f_{\text{obs}}}{2} \right\} = f_S - f_{\text{obs}}$$

(A36)

This expression can be readily rearranged to generate a relationship between the flux measured at the support electrode and that corresponding to the reaction within the enzyme layer, as follows:

$$f_{\text{obs}} = \frac{1 + \Phi/2}{1 + \Phi} f_S = \eta f_S$$

(A37)

Hence, we note that the $\eta$-function is given specifically by:

$$\eta = \frac{1 + \Phi/2}{1 + \Phi}$$

(A38)

A plot of $\eta$ versus $\Phi$ is outlined in Figure A1. We note that when $\Phi << 1$, then $\eta \approx 1$, and the observed flux corresponding to the oxidation of the substrate at the electrode surface will equal that of the substrate formation reaction catalyzed by the immobilized enzyme within the membrane. This situation will arise when the diffusive flux $f_{DS}$ of the substrate through the diffusion layer is much less than the diffusive flux $f_{DS}^\prime$ of substrate species through the enzyme layer to the support electrode surface. In these circumstances, very little substrate is lost from the membrane. In contrast, we note that when $\Phi >> 1$, then substrate produced at the enzyme surface will be lost from the membrane and $\eta \to \frac{1}{2}$. Here, the substrate $S$ generated via the catalysed transformation of $P$ at the enzyme surface is lost rapidly from the membrane and diffuses into solution. From Figure A1, we note that $\eta$ has a maximum value of unity and a minimum value of 0.5, and $\eta$ decreases regularly as $\Phi$ increases in value, reflecting the increasing loss of substrate from the membrane. Hence, we can view the $\eta$ parameter as an efficiency factor which will affect the substrate amplification and which depends on the ratio of the diffusive fluxes of substrate within the enzyme membrane and through the solution phase.
