The Enhanced Gaussian Noise Model extended to Polarization-dependent Loss
Paolo Serena, Member, IEEE, Chiara Lasagni, and Alberto Bononi, Senior Member, IEEE

Abstract—We show how to extend the enhanced Gaussian noise (EGN) model to account for polarization-dependent loss (PDL) of optical devices placed along a fiber-optic link. We provide a comprehensive theory highlighting the relationships between the time, frequency, and polarization domains in the presence of fiber nonlinear Kerr effect and amplified spontaneous emission. We double-check the new model with split-step Fourier method (SSFM) simulations showing very good accuracy. The model can be efficiently exploited to estimate low values of outage probabilities induced by PDL with computational times orders of magnitude faster than the SSFM, thus opening new opportunities in the design of optical communication links.

Index Terms—Polarization-dependent loss (PDL), Gaussian-noise (GN) model, enhanced-GN (EGN) model.

I. INTRODUCTION

Polarization-dependent loss (PDL) expresses the dependence of the loss of an optical device on the state of polarization of the input electromagnetic field [1]. PDL induces crosstalk between the polarization tributaries and an unequal loss of energy, which are particularly detrimental in polarization-division multiplexing (PDM) transmissions.

Although typical optical fibers show negligible PDL, PDL may be relevant in optical devices, such as the Erbium-doped fiber amplifiers (EDFA) and inside the wavelength selective switches (WSS) of reconfigurable optical add/drop multiplexers (ROADM) [2].

The axes of maximum/minimum PDL fluctuate randomly over times much longer than the coded data block duration, thus making the optical channel stochastic and non-ergodic. Hence the analysis with PDL should not focus on the average performance, such as the average signal-to-noise ratio (SNR), but rather on the statistics of the SNR. Of particular concern is the outage probability, i.e., the probability that the SNR falls below a given threshold. Because of the random fluctuations, the problem of estimating such as probability is particularly challenging, especially in numerical simulations where low outage values call for many time-consuming simulations, but also in experiments where collecting many observations may require a huge amount of resources to save and post-process the results.

Such difficulties stimulated the development of theoretical models for quick estimation of the PDL effects. Most of the literature focused on the interplay between PDL and amplified spontaneous emission (ASE) noise in the linear regime. Remarkable results have been provided by Gisin [3], who found the statistics of the resulting PDL after concatenation of many devices, and by Mecozzi and Shtaif [4] that investigated the asymptotic properties of PDL showing its Maxwellian statistics when expressed in dB. The implications of the interplay PDL-ASE on the SNR have been investigated by the same authors in [5] and by Shtaif in [6]. The implications of PDL on the channel capacity has been investigated by Nafta et al. in [7]. A quaternion approach to analytically investigate PDL has been proposed by Karlsson and Petersson in [8].

The interplay between PDL and the fiber nonlinear Kerr effect received much less analytical attention, and most of the literature focused on numerical/experimental investigations [9]–[16]. Such investigations showed contrasting results, since PDL showed limited interaction with the Kerr effect in [13] while a non-negligible interaction has been pointed out, for instance, in [11], [14].

In modern optical communication systems, it is customary to analyze the performance of the link by employing perturbative models because of their simplicity. Among the available models in the literature, particular attention has been captured by the Gaussian noise (GN) model [17] and its advanced version, the enhanced Gaussian noise (EGN) model [18], [19], also referred to as nonlinear interference noise (NLIN) model [20]. Such models showed excellent accuracy in a wide range of optical links, with savings in computational time of more than an order of magnitude compared with traditional models, such as the split-step Fourier method (SSFM).

We extended the scalar theory of the GN model by including polarization effects in [21], and first included PDL in the GN model framework in [22] for a quick estimation of the probability density function (PDF) of the nonlinear interference (NLI).

In this work, besides providing a novel mathematical formalism to cope with PDL in the GN model, we show how to account for PDL even in the EGN model. The general theory will be double-checked against SSFM simulations.

The advantages of using the new model as well as some interesting implications, such as the scaling of the outage probability with power, will be discussed.

The paper is organized as follows: in Section II we show the main theory, based on some results provided in the...
Appendices; in Section III we validate the model. Finally, in Section IV we draw our main conclusions.

II. PDL-EXTENDED EGN MODEL

We adopt the following bra-ket notation
\[ |\tilde{A}(\omega)\rangle \triangleq \begin{bmatrix} \tilde{A}_x(\omega) \\ \tilde{A}_y(\omega) \end{bmatrix}, \quad \langle \tilde{A}(\omega)| \triangleq \begin{bmatrix} \tilde{A}_x^*(\omega) \\ \tilde{A}_y^*(\omega) \end{bmatrix} \]

where \(\tilde{A}_{x,y}(\omega)\) indicate the Fourier transform of the two polarization tributaries of the transmitted electric field, with \(\omega\) the angular frequency.

Under a first-order perturbative approximation, the received electric field \(|\tilde{A}_R(\omega)\rangle\) can be related to the transmitted one \(|\tilde{A}(\omega)\rangle\) by [23]:
\[ |\tilde{A}_R(\omega)\rangle \approx T(z,\omega) (|\tilde{A}(\omega)\rangle + |\tilde{n}(\omega)\rangle + |\tilde{\eta}(\omega)\rangle) \quad (1) \]

with \(|\tilde{n}(\omega)\rangle\) and \(|\tilde{\eta}(\omega)\rangle\) the ASE noise and the signal NLI, respectively, and \(T(z,\omega)\) a \(2 \times 2\) matrix accounting for all linear impairments from input to coordinate \(z\). Such a matrix can be separated into a scalar and a polarization-dependent contribution:
\[ T(z,\omega) = e^{\vartheta(z,\omega)} U(z) \]
\[ \vartheta(z,\omega) \triangleq -\int_z^\infty \left( \frac{\alpha(\xi)}{2} + j\beta(\xi,\omega) \right) d\xi \quad (2) \]

with \(\alpha\) the attenuation factor and \(\beta\) the imaginary part of the propagation constant. The matrix \(U\) accounts for a frequency-independent PDL accumulated up to coordinate \(z\). We assume lumped PDL (e.g., WSS and EDFA) at coordinates \(z_p : p = 0, \ldots, N-1\), with \(z_0 = 0\). The matrix \(U\) depends on the \(k\)th device at coordinate \(z_k \leq z\) with PDL matrix \(M_k\) by [1]:
\[ U(z) = M_p M_{p-1} \cdots M_0, \quad z_p < z < z_{p+1} \]
\[ M_k \triangleq W_k \left[ \begin{array}{cc} \sqrt{1 + \Gamma_k} & 1 \\ 0 & \sqrt{1 - \Gamma_k} \end{array} \right] W_k^\dagger \quad (3) \]

where \(\dagger\) indicates transpose-conjugate, the \(W_k\) are matrices uniformly distributed in the set of the \(2 \times 2\) unitary random matrices (Haar matrices), while \(\Gamma_k\) defines the PDL \(\rho_k\) by \(\rho_k \triangleq (1 + \Gamma_k) / (1 - \Gamma_k)\). The PDL is usually expressed in dB by \(20 \log_{10}(\rho_k)\).

In the case of many identically distributed PDL elements, the resulting PDL of the link, expressed in dB, follows a Maxwellian distribution [4] with an average value scaling with \(\sqrt{N}\).

Matrix \(W_k\) is statistically independent of matrix \(W_n\), with \(k \neq n\). Such matrices are slowly varying in time compared to the symbol timing, hence while each polarization tributary preserves its average power while crossing the generic PDL element, each PDM data-block experiences a power unbalance between polarization tributaries. Such an imbalance can be removed at the receiver side by performing linear equalization, for instance by the zero-forcing equalizer \(T^{-1}(z,\omega)\).

However, PDL remains both in the ASE and the NLI. Fig. 1 sketches the idea for ASE. In this work, we assume \(W_k\) a random variable, thus time-independent.

![Fig. 1. Sketch of the effects experienced by the signal |\(A\rangle\) and the ASE |\(\tilde{\eta}\rangle\) along propagation. The zero-forcing equalization assumption is equivalent to a round-trip propagation of the signal, thus returning equal to itself at reception. However, ASE follows an incomplete round-trip, resulting in PDL.](image)

The received ASE \(|\tilde{\eta}(\omega)\rangle\) is related to the ASE \(|\tilde{\eta}_m(\omega)\rangle\) going out the in-line amplifier at coordinate \(z_m\) by:
\[ |\tilde{\eta}(\omega)\rangle = \sum_{m=1}^{M} M_{0}^{-1} M_{1}^{-1} \cdots M_{m-1}^{-1} |\tilde{\eta}_m(\omega)\rangle \quad (4) \]

with \(M\) the number of amplifiers. For instance, concerning Fig. 1 referred to an ideal source, i.e., \(M_0 = I\) with \(I\) the identity matrix, we have:
\[ |\tilde{\eta}(\omega)\rangle = |\tilde{\eta}_1(\omega)\rangle + M_1^{-1} |\tilde{\eta}_2(\omega)\rangle + M_1^{-1} M_2^{-1} |\tilde{\eta}_3(\omega)\rangle = |\tilde{\eta}_1(\omega)\rangle + U(z_1)^{-1} |\tilde{\eta}_2(\omega)\rangle + U(z_2)^{-1} |\tilde{\eta}_3(\omega)\rangle \quad (5) \]

In Appendix A we show that the NLI takes the expression:
\[ |\tilde{n}(\omega)\rangle = \sum_{p=0}^{\infty} \sum_{n=0}^{N-1} n_p (\omega, \omega_1, \omega_2) \times \langle \tilde{A}(\omega + \omega_1 + \omega_2) | P(z_p) | \tilde{A}(\omega + \omega_2) \rangle |\tilde{A}(\omega + \omega_1)\rangle d\omega_1 d\omega_2 \quad (6) \]

with \(n_p\) the kernel of the optical fiber in the segment \([z_p, z_{p+1}]\), and \(P(z_p) \triangleq U(z_p) U^\dagger(z_p)\). Please note that, without PDL, \(P = I\). Eq. (6) clearly shows the four-wave mixing (FWM) process generating the NLI.

Both the NLI and the ASE accumulate linearly with the propagation distance, both being additive under the model assumptions. Moreover, by comparing (4) and (6), we observe that after zero-forcing equalization they both depend on the PDL accumulated before their generation. However, such a dependence follows completely different relationships. In particular, the quadratic dependence on the entries of matrix \(U(z_p)\) in the NLI is expected to induce larger random fluctuations of the SNR compared to the linear dependence in the ASE case.

We now introduce a discrete-time channel model relating the transmitted/received data symbol [23]. We assume \(|A(t)\rangle\) is a wavelength division multiplex (WDM) of linearly modulated digital signals:
\[ |A(t)\rangle = \sum_{n=-\infty}^{\infty} \sum_{h=1}^{\# \text{channels}} \sum_{k \in (x,y)} a_{n,h,k} p_h(t - nT_h) e^{j\Omega_h t} |k\rangle \quad (7) \]

where \(a_{n,h,k}\) is the digital symbol (e.g., quadrature amplitude modulation, QAM) at time \(n\), WDM channel-index \(h\), and
polarization $k$; $p_k(t - nT_h)$ is the supporting pulse at the $n$th symbol time of duration $T_h$ and modulated at carrier frequency $\Omega_h$. We find it useful to compact the notation by calling $a_n$ the generic (scalar) information symbol per $(\text{time, frequency, space})$ channel use, where the vector $n$ should be read as:

$$n = [n_1, n_2, n_3]^{\text{space}}_{\text{time}}$$

(8)

We will refer to $a_n$ as an atom of the source information. This way, by adopting signal-space representation concepts, eq. (7) in the Fourier domain can be written as:

$$|\hat{A}(\omega)| = \sum_n a_n |\hat{G}_n(\omega)|$$

(9)

where $\sum_n$ stands for all summations in (7) and the basis functions:

$$|\hat{G}_n(\omega)| = \hat{p}_{n_2}(\omega - \Omega_n) e^{-j(\omega - \Omega_n)n_1T_n} n_3$$

We assume the detector performs demodulation, matched filtering, sampling and average carrier phase recovery. In our framework, the first three operations correspond to the inner product $\int_{-\infty}^{\infty} \langle \tilde{G}_1(\omega) | \hat{A}(\omega) \rangle \, \frac{d\omega}{2\pi}$. In particular, such operation results in $a_i$ in absence of impairments when using orthonormal basis functions, such as root-raised cosine pulses with non-overlapping spectrum among channels:

$$\sum_n a_n \int_{-\infty}^{\infty} \langle \tilde{G}_1(\omega) | \hat{G}_n(\omega) \rangle \, \frac{d\omega}{2\pi} = a_i$$

(10)

By following similar steps as [23], [24], from (1) we get the following discrete-time channel model relating the transmitted atom $a_i$ to the received one $u_i$:

$$u_i = a_i + w_i + n_i$$

where $w_i$ and $n_i$ are the sampled ASE and NLI, respectively:

$$w_i = \int_{-\infty}^{\infty} \langle \tilde{G}_1(\omega) | \tilde{w}(\omega) \rangle \, \frac{d\omega}{2\pi}$$

$$n_i = -j \sum_{k,m,n} a^*_k a_m a_n X_{kmni}$$

(11)

$X_{kmni}$ is a tensor weighting the four-atom mixing (FAM) at the symbol level:

$$X_{kmni} = \sum_{p=0}^{N-1} \int\int\int_{-\infty}^{\infty} \eta_p(\omega, \omega_1, \omega_2) \times \langle \tilde{G}_k(\omega + \omega_1 + \omega_2) | P(z_p) \tilde{G}_m(\omega + \omega_2) \rangle \times \langle \tilde{G}_1(\omega) | \tilde{G}_n(\omega + \omega_1) \rangle \, \frac{d\omega_1}{2\pi} \, \frac{d\omega_2}{2\pi} \, \frac{d\omega}{2\pi}$$

$$= \sum_{p=0}^{N-1} P_{k_3m_3}(z_p) \delta_{k_2n_2} S_{kmni}(z_p)$$

where the $\delta$ indicates Kronecker’s delta, and in the final identity of (12) we expanded the tensor in terms of the tensor $S_{kmni}$ weighting the FWM interaction at the scalar level:

$$S_{kmni}(z_p) \triangleq \int\int\int_{-\infty}^{\infty} \eta_p(\omega_1, \omega_2) \times \langle \tilde{G}^*_k(\omega + \omega_1 + \omega_2) \tilde{G}_m(\omega + \omega_2) \tilde{G}^*_1(\omega) \tilde{G}_n(\omega + \omega_1) \rangle \, \frac{d\omega_1}{2\pi} \, \frac{d\omega_2}{2\pi} \, \frac{d\omega}{2\pi}$$

(13)

where $\tilde{G}_n(\omega)$ is defined in implicit form by $|\tilde{G}_n(\omega)| = |\tilde{G}_n(\omega)| m_3$. It is worth noting that in the special, yet relevant, case of a homogeneous link in absence of PDL, the summation $\sum_p$ in (12) can be closed with some advantage for numerical purposes and simplicity.

We now evaluate the covariance of ASE and NLI atoms when acting alone.

### A. ASE variance

The PDL impact on ASE has been investigated in several papers in the literature [8], [6], [9], [1], whose main results we now rephrase in our notation.

By definition, the variance of the ASE atom $i$ is $\sigma^2_{\text{ASE}} = \mathbb{E}[u_i^2]$, with $\mathbb{E}$ indicating expectation. We evaluate it focusing on a link with independent and identically distributed ASE sources, hence with [25, p. 418]:

$$\mathbb{E}[|\tilde{w}_m(\omega)| \langle \tilde{w}_p(\mu) |] = \frac{N_0}{2} \delta(\omega - \mu) \delta_{mp} I$$

(14)

where the two $\delta$ indicate Dirac/Kronecker’s delta, while $N_0$ is the one-sided, dual-polarization, power spectral density (PSD) of ASE per amplifier. $N_0$ is related to the noise figure $F$ and the gain $G$ by $N_0 = h\nu FG$, with $h$ Planck’s constant and $\nu$ carrier frequency.

Let $B$ be the noise equivalent bandwidth of the receiver. By using (4) and the orthogonality property (10) in (14) we have:

$$\sigma^2_{\text{ASE}} = \frac{N_0B}{2} \sum_{p=1}^{M} P_{1i1i}^{-1}(z_p)$$

(15)

with $M$ the number of optical amplifiers in the link. Please note that the matrices $P_{1i1i}(z_p)$ and hence their elements $P_{1i1i}(z_p)$ are not independent but related by the concatenation rule of PDL [8].

With PDL it is more interesting to deal with the SNR per polarization, because of the asymmetrical behavior of noise power. With reference to the generic polarization $i$:

$$\text{SNR}^i_{\text{ASE}} = \frac{S_i}{\sigma^2_{\text{ASE}}} = \frac{\text{SNR}^i_{\text{ASE}}(\text{PDL}=0)}{1/M \sum_{p=1}^{M} P_{1i1i}^{-1}(z_p)}$$

(16)

where $S_i$ is the signal power on polarization $i$ and $\text{SNR}^i_{\text{ASE}}(\text{PDL}=0) = S_i / (N_0MB)$. The denominator of (16), equal to the span-average of $P_{1i1i}^{-1}$, is the random PDL loss/gain per polarization.
B. NLI variance

The FWM process underpinning the NLI is formally identical to the scalar case, with just a different weighting tensor. However, some symmetries cease to hold, hence the master theorem at the heart of the EGN model (see Appendix B) must be properly generalized by taking care of such a novelty. We observe the following symmetries in indexing:

\[ X_{kmni} = X_{nkmi}^* \] (always)
\[ X_{kmni} = X_{kmni}^* \] (no PDL).  \( (17) \)

The breakdown of the last symmetry induces a small modification in the master theorem as detailed in Appendix B.

With such ingredients, after carrier phase estimation the variance of the NLI atom \( n_i^2 \), \( \sigma_{n_i}^2 = \mathbb{E}[n_i^2 n_i^*] \), can be found by plugging (12) into the master theorem (28). Such a variance can be split into the GN, fourth-order noise (FON) [23], and higher-order noise (HON) [18–20] contributions:

\[ \sigma_{\text{NLI}}^2 = \sigma_{\text{GN}}^2 + \sigma_{\text{FON}}^2 + \sigma_{\text{HON}}^2. \]

We now analyze the contributions for independent and identically distributed data symbols. The result depends on the statistical cumulants of the symbols [19], which are related to the main moments \( \mu_n \triangleq \mathbb{E}[n_k^n] \) by:

\[ \begin{align*}
\kappa_1 &= \mu_2 \\
\kappa_2 &= \mu_4 - 2\mu_2^2 \\
\kappa_3 &= \mu_6 - 9\mu_4\mu_2 + 12\mu_3^2.
\end{align*} \]

1) **GN term**: As outlined in Appendix B, the GN contribution to the variance of polarization \( i_3 \in (x, y) \) is:

\[ \sigma_{\text{GN}}^2 = \kappa_1^2 \sum_{k,m,n} X_{kmni} \left( X_{kmni}^* + X_{kmni}^x \right) \]
\[ = \kappa_1^2 \sum_{k,m,n} \delta_{i_3 i_5} \sum_{p,l=0}^{N-1} S_{knmi} (z_p) S_{knni} (z_l) \]
\[ \times \left( P_{k_3 m_3} (z_p) P_{k_3 m_3}^* (z_l) + \delta_{k_3 l_3} P_{k_3 m_3} (z_p) P_{k_3 m_3}^* (z_l) \right) \]
where we used (12). Such a result can be easily generalized to the spatial-covariance matrix. We introduce the 2 \( \times 2 \) GN covariance matrix between the polarizations, \( K_{\text{GN}} : K_{i_3 j_3}^{\text{GN}} = \mathbb{E}[n_i^2 n_j^*] \), \( i_{1,2} = j_{1,2} \), \( (i_3, j_3) \in (x, y) \), which takes the elegant form [22]:

\[ K_{\text{GN}} \triangleq \left[ \begin{array}{cc} \text{var} (\text{NLI}^{\text{GN}}) & \text{cov} (\text{NLI}^{\text{GN}} \text{NLI}^y_{y}) \\ \text{cov} (\text{NLI}^x_{x} \text{NLI}^y_{y}) & \text{var} (\text{NLI}^y_{y}) \end{array} \right] \]
\[ = \sum_{p,l=0}^{N-1} \rho_{\text{GN}} (p, l) \left( \text{Tr} \left[ P (z_p) P (z_l)^* \right] I + P (z_p) P (z_l)^* \right) \]
(18)
\[ = \sum_{p,l=0}^{N-1} \rho_{\text{GN}} (p, l) \end{align*} \]

where \( \rho_{\text{GN}} (p, l) \triangleq \sum S_{knmi} (z_p) S_{knni}^* (z_l) \), with the summations limited to the temporal and frequency indexes, is the *scalar* cross-correlation between the NLI accumulated in trunk \( p \) and trunk \( l \), while \( \text{Tr} \) indicates the trace of a matrix. It is worth noting that in absence of PDL we have [23], [20]:

\[ \sigma_{\text{GN}}^2 \text{(no PDL)} = \sum_{p,l=0}^{N-1} \rho_{\text{GN}} (p, l) \end{align*} \]
\[ \times \left| \tilde{P}_r (\omega - \Omega) \right|^2 \left| \tilde{P}_r (\omega + \omega_1 + \omega_2 - \Omega) \right|^2 \]
\[ \times \left| \tilde{P}_s (\omega + \omega_2 - \Omega) \right|^2 \left| \tilde{P}_s (\omega + \Omega) \right|^2 \frac{\mathrm{d} \omega_1 \mathrm{d} \omega_2}{2\pi} \frac{\mathrm{d} \omega_1 \mathrm{d} \omega_2}{2\pi} . \]
(19)

where the term \( \eta \) is the fiber-kernel of the entire link, see Appendix A. We also observe that, since without PDL \( P (z_p) = I \) for each \( p \), it is \( K_{\text{GN}} = 3 \mathbf{I} \) [19].

The right-hand side in (19) is well known in the literature, see, e.g., [23]. The main contribution of this work is that eq. (18) generalizes the scalar result (19) to the case with PDL. We note that now we need to know all trunk cross-correlations, while in the scalar case such information was not required. However, the matrix of elements \( \rho_{\text{GN}} (p, l) \) is a Toeplitz matrix, hence it can be calculated in a short simulation (preload), usually of the order of seconds, for instance with the algorithm [20]. Once \( \rho_{\text{GN}} \) is available, the PDL statistics can be evaluated very quickly by computing the matrix in (18).

The SNR of the generic polarization \( i \) finally is [17]:

\[ \text{SNR}_{\text{GN}} \triangleq \frac{1}{K_{ii}^{\text{GN}}} S_{ii} \]
\[ i \in (x, y) \]  \( (20) \)

which, contrary to ASE, cannot be expressed in closed-form in terms of the SNR without PDL.

2) **FON terms**: The FON variance of polarization \( i_3 \in (x, y) \) is derived in Appendix B, here repeated for convenience:

\[ \sigma_{\text{FON}}^2 = \kappa_2^2 \sum_{k,n} \left( |X_{knmi} |^2 + |X_{knki}^x |^2 \right) . \]  \( (21) \)

In Appendix B we label the first absolute value in (21) by F4 and the second by Q4. With similar steps done for the GN counterpart, we introduce the FON covariance matrix \( K_{\text{FON}} \) between spatial coordinates. After inserting (12) in (21) we obtain:

\[ K_{\text{FON}} = \sum_{p,l=0}^{N-1} \left( \rho_{\text{FON}} (p, l) F (z_p, z_l) + \rho_{\text{FON}} (p, l) Q (z_p, z_l) \right) \]

where \( \rho_{\text{FON}} (p, l) \triangleq \sum S_{knki} (z_p) S_{knki}^* (z_l) \) and \( \rho_{\text{FON}} (p, l) \triangleq \sum S_{nkki} (z_p) S_{nkki}^* (z_l) \), with the summations limited to the temporal and frequency indexes, are the scalar cross-correlations between the two kinds of FON (see Appendix B) accumulated in trunk \( p \) and trunk \( l \). They can be evaluated with the scalar EGN model [20], [18], [19].

Matrices \( F \) and \( Q \) are the novelty introduced by PDL. They have the following entries:

\[ F_{11} = 4P_{11} (z_p) P_{11}^* (z_l) + P_{22} (z_p) P_{22}^* (z_l) + P_{12} (z_p) P_{12}^* (z_l) \]
\[ F_{12} = P_{22} (z_p) P_{12}^* (z_l) + P_{12} (z_p) P_{21}^* (z_l) \]
\[ F_{21} = P_{12} (z_p) P_{21}^* (z_l) + P_{21} (z_p) P_{22}^* (z_l) \]
\[ F_{22} = 4P_{22} (z_p) P_{22}^* (z_l) + P_{11} (z_p) P_{11}^* (z_l) + P_{21} (z_p) P_{21}^* (z_l) \]
while matrix $Q$:

$$Q_{11} = P_{11}(z_p)P_{11}^*(z_\ell) + P_{21}(z_p)P_{21}^*(z_\ell)$$
$$Q_{12} = Q_{21} = 0$$
$$Q_{22} = P_{22}(z_p)P_{22}^*(z_\ell) + P_{12}(z_p)P_{12}^*(z_\ell).$$

Please note that in absence of PDL we have $F = 5\mathbf{I}$ and $Q = \mathbf{I}$, as expected [19]. It is worth noting that in most of the optical links the dominant FON term is the one related to the F4 term.

3) HON term: The HON is a sixth order term, labeled by Q6 in Appendix B. Such a term occurs only when all the six atoms joining the NLI covariance are identical. We have:

$$\sigma_{HON}^2 = \kappa_3 \sum_n |\mathcal{X}_{nnn}|^2.$$

We introduce a HON covariance matrix $K_{HON}$ between spatial coordinates obtaining:

$$K_{HON} = \sum_{p,\ell=0}^{N-1} \rho_p(\ell)H(z_p, z_\ell)$$

with $\rho_p$ the scalar HON cross-correlation between trunk $p$ and trunk $\ell$, while matrix $H$ has entries:

$$H_{ii} = P_{ii}(z_p)P_{ii}^*(z_\ell), \quad i = 1, 2$$
$$H_{ij} = 0, \quad i \neq j.$$

Please note that in absence of PDL we have $H = \mathbf{I}$. In most of the optical links, the HON term is dominated by the FON term.

Finally, the SNR associated to the NLI is:

$$\text{SNR}_{NLI}^i = \frac{1}{(K_{ii}^{\text{FON}} + K_{ii}^{\text{HON}} + K_{ii}^{\text{PDL}}) S_i^2}, \quad i \in (x, y)$$

while the overall SNR, by neglecting ASE-NLI interaction, follows the usual concatenation rule:

$$\frac{1}{\text{SNR}^2} = \frac{1}{\text{SNR}_{\text{ASE}}^2} + \frac{1}{\text{SNR}_{\text{NLI}}^2}. \quad (22)$$

III. NUMERICAL VALIDATION

We checked the proposed model against SSFM based simulations. Common parameters to all simulations are the pulse types, i.e., root-raised cosine pulses with roll-off 0.01 sent at 49 Gbaud, the channel spacing, 50 GHz, and the optical fibers, i.e., single-mode fibers (SMF) having length 100 km, dispersion $D = 17$ ps/nm/km, attenuation $\alpha = 0.2$ dB/km, nonlinear coefficient $\gamma = 1.26$ 1/W/km. The channel under test (CUT) is in any case the central channel of the WDM.

Since the inclusion of PDL in the NLI is the main novelty of this work, in a first test we focused on the above system without ASE. The WDM was made of $11 \times 50$ GHz channels, PDM-modulated with Gaussian distributed symbols, i.e., the capacity-achieving modulation format for the additive white Gaussian noise (AWGN) channel. In this case, the EGN model degenerates into the GN model [22].

PDL was included at each amplifier with a value of 0.5 dB. The residual dispersion per span was either 30 ps/nm (dispersion-managed, DM30) or absent (dispersion uncompensated, DU). In any case, full dispersion compensation was implemented at the receiver input after propagation over 10 or 20 spans. Polarization-mode dispersion was neglected since expected to be of minor concern [12].

The link was simulated by the SSFM and compared with the prediction of the PDL-EGN model. In the PDL-EGN matched filtering, zero-forcing PDL equalization and carrier phase estimator (CPE) are implicit in the model. On the other hand, in the SSFM case we implemented matched filtering followed by a 1-tap zero-forcing equalizer, and by a CPE recovering the average phase induced by the fibers.

We estimated the PDF of the received SNR by Monte Carlo simulations over the PDL seeds, both with SSFM runs and with the PDL-EGN model. In the SSFM case, we used 1000 different random PDL realizations. For each realization, we varied the random state of polarization of the channel lasers as well. The SSFM symmetric-step was chosen according to the local-error criterion with a first step accumulating a FWM phase of 20 rad [26]. The number of symbols was 65536, sufficiently high to capture the largest walk-off among channels and to have a negligible error from the Monte Carlo estimation [14]. In the PDL-EGN, besides the Monte Carlo iterations over the PDL seeds, we numerically solved the frequency integrals by another Monte Carlo sampling.

![PDF estimate](image-url)  
**Fig. 2.** Estimate of the PDF of the SNR per polarization by SSFM simulations (triangles for DM30, circles for DU) and the corresponding (almost overlapped) PDL-GN PDFs (solid lines).

Fig. 2 depicts the estimate of the PDF of the SNR per polarization by SSFM (symbols) and the PDL-GN model (20, lines). We investigated two links lengths, 10 and 20 spans. In order to compare the two links, we plotted the PDFs versus the SNR offset from its mean. For each link, the mean SNR of SSFM simulations was within 0.1 dB of that from the PDL-GN model.

We observe an excellent fit at both distances, thus confirming the validity of the proposed model. In particular, we note that dispersion management does not affect the PDF shape, while it strongly impacts the average value because of strongly different correlations of the NLI among spans.

In a second test, we investigated a more realistic distribution of PDL along the optical link. We thus focused on a 3200 km network scenario where the CUT, besides being added
and dropped by ROADMs, crosses ROADMs placed every 4 spans. Within each ROADM working in bypass mode, two WSS were crossed. The PDL was 0.1 dB within EDFAs and 0.4 dB within the WSS, respectively [15]. Fig. 4 sketches the link.

The modulation format was PDM-star 8QAM, for a total of 21 channels. In this setup we included ASE, with a noise figure of 5 dB per amplifier. It is worth noting that with ideal equalization the last drop impacts equally ASE, NLI, and signal, hence with no implications on the statistics.

The PDF estimated by the PDL-EGN and by SSFM at power 1 dBm maximizing the SNR is reported in Fig. 3. Again, we observe a good match between the two models. Even if not shown in the figure, we observed a bias of 0.1 dB by the PDL-EGN model.

Having tested the validity of the model, we applied it to estimate the outage probability, here defined as the probability that the SNR falls below the threshold of 10.56 dB, corresponding to a Q-factor of 6.5 dB. At such a threshold the achievable information rate of a symbol-by-symbol star-8QAM detector in AWGN is 2.84 bits/symbol. Since the loss to the nominal 3 bits/symbol carried out by the modulation format is 0.16 bits/symbol, the transmission is expected to be feasible with realistic forward-error correcting (FEC) codes. Moreover, since the Shannon capacity at such threshold is 3.63 bits/symbol, the modulation format is a good candidate for transmission over 3200 km.

Fig. 5(bottom) reports the outage probability versus launched power per channel, and for reference Fig. 5(top) also shows the mean SNR versus the same power. Several interesting observations can be drawn from Fig. 5. First, we observe that the minimum outage probability is $3 \times 10^{-4}$, a non-negligible value indicating the importance of including PDL in link design. Second, the best power for the mean SNR does not coincide with the best power for the outage probability, with a gap of 0.4 dB. This is strictly related to the nonlinear relation between the outage probability and the SNR. Third, it is interesting to compare the slope of the asymptotes in the ASE-dominated regime (linear regime) and the NLI-dominated regime (nonlinear regime). In the mean SNR curve, we observe a slope of +1 dB/dB in the linear regime and -2 dB/dB in the nonlinear regime. A factor 2 in absolute terms between the two slopes is well known and related to the scaling properties of the ASE and the NLI variance [27]. Quite surprisingly, we still observe a factor 2 between the slopes of the asymptotes on the outage probability graphs. Such an observation can be very useful for quickly scaling the outage probability with power.

In Fig. 6 we compare the individual contributions of ASE and NLI to SNR statistics. We set the power to 2 dBm, i.e., where the two effects yield the same average variance. Symbols indicate SSFM simulations. We observe that, in this setup, the PDF of the ASE-only case is slightly larger than that of the NLI-only case, although the average values are similar. Most important, the ASE-only and the NLI-only PDFs have different shapes, hence the NLI cannot be treated as an equivalent extra-ASE distributed along the link.

It is worth noting that if instead of plotting the per-
polarization SNR PDF, we plot the PDF of the overall PDM SNR, as usually done in the literature, we obtain a sharply different behavior, as depicted in Fig. 7 with the PDL-EGN model. The PDM SNR, or simply SNR, is defined as $\text{SNR} = (S_x + S_y)/(\sigma_x^2 + \sigma_y^2)$, with $\sigma_x^2, \sigma_y^2$ the variance of the noise under investigation. The reason for the differences is related to the antithetic impact of PDL on the $x$ and $y$ ASE variances, which is not manifested by SPM- and XPM-like nonlinear effects, respectively.

It is interesting to compare the computational times of the PDL-EGN model and the SSFM. As a reference, an SSFM simulation, with step set-up as in [26], took 1 day to run 125 PDL seeds on a cluster using INTEL XEON E5- 2683v4 2.1GHz 32 cores central processing units (CPU) with 128 GB of RAM and NVIDIA Tesla P100 graphics processing unit (GPU). The same seeds have been simulated in a fraction of second with the PDL-EGN, plus an overhead for the computation of the span cross-correlations of the order of seconds for the PDL-GN and few minutes for the PDL-EGN. Not surprisingly, with the EGN we were able to simulate $10^6$ PDL seeds, while with SSFM only $10^3$.

IV. Conclusions

We extended the EGN model to include PDL. The extension forced us to rework the whole EGN theory, yielding a formally compact master equation based on tensors able to span the time, frequency and polarization axes. With the new model, it is possible to estimate the statistics of the SNR in the nonlinear regime by exploring very rare events. Our results show that the NLI interplay with PDL follows a different behavior than the one experienced by ASE and thus needs a proper description. Besides this aspect, probably the main advantage of the novel model relies on its extremely fast computational time compared to standard algorithms, such as the SSFM. For instance, we investigated 1000 different optical links with random PDL in a fraction of second after a pre-processing of the order of seconds to minutes. Such times are inaccessible to SSFM simulations. The model can now be used to include PDL precisely in the design of optical links, while today the problem is approximately solved by allocating empirical margins to PDL. This way, it is possible to perform the design optimizing the system outage probability instead of the average performance.

Appendix A

Nonlinear interference

In the absence of polarization-mode dispersion, the optical propagation within an optical fiber is well described by the Manakov equation. A first-order perturbative solution of the Manakov equation is [23], [17], [20], [19]:

$$|A(z, t)| \simeq e^{Lz} |A(0, t)| + \int_0^z e^{L(z-\xi)} \mathcal{N} (e^{L\xi} |A(0, t)|) d\xi.$$  \hspace{1cm} (23)

where the operator $L$ accounts for linear effects while $\mathcal{N}$ for nonlinear effects, respectively. $L$ is best defined in the frequency domain by its Fourier transform $\mathcal{F} \{ e^{L\xi} \} \triangleq e^{\bar{L}(z, \omega)}$, with $\bar{\theta}$ accounting for attenuation and dispersion, see (2). $\mathcal{N}$ is best described in the time domain $t$, i.e.,

$$\mathcal{N} \triangleq - j \gamma \frac{8}{9} \langle A(z, t)|A(z, t)\rangle |A(z, t)|.$$  \hspace{1cm} (24)

The integral in (23) defines the NLI whose physical interpretation is simple: the NLI is additive along distance, and its generic contribution generated at coordinate $\xi$ depends on the unperturbed signal up to that coordinate and experiences only linear effects up to the end [19]. If we factor out $e^{Lz}$ and apply zero-forcing equalization, i.e., concatenation with the inverse $e^{-Lz}$, the received signal $|A_R\rangle$ is:

$$|A_R\rangle \simeq |A(0, t)| + \int_0^z e^{-L\xi} \mathcal{N} (e^{L\xi} |A(0, t)|) d\xi.$$  \hspace{1cm} (24)

which further suggests interpreting the NLI as an infinite summation of echoes.

The Fourier transform $|\tilde{n}(\omega)\rangle$ of the NLI in (24) is:

$$|\tilde{n}(\omega)\rangle = -j \int_{-\infty}^{\infty} \eta(\omega, \omega_1, \omega_2) \times$$

$$\langle \tilde{A}(\omega + \omega_1 + \omega_2)|\tilde{A}(\omega + \omega_2)\rangle |\tilde{A}(\omega + \omega_1)\rangle \frac{d\omega_1 d\omega_2}{2\pi 2\pi}.$$
with the kernel of the optical link in \((0, z)\) given by:

\[
\eta(\omega, \omega_1, \omega_2) = \frac{8}{9} \gamma \int_0^z e^{ \theta(\xi, \omega_1 + \omega_2)} e^{ \theta(\xi, \omega_1 + \omega_2) - \theta(\xi, \omega)} d\xi .
\]  

(25)

It is worth noting that for optical fibers with constant parameters the integral in \(\xi\) can be given in closed form [17].

Inserting a frequency-independent PDL in the model corresponds to applying the substitutions \(e^{\varepsilon \xi} \rightarrow e^{\varepsilon \xi} \text{U}(z)\) and \(e^{-\varepsilon \xi} \rightarrow e^{-\varepsilon \xi} \text{U}^{-1}(z)\), with \(\text{U}\) accounting for the cumulative PDL up to coordinate \(z\), as per (2). With lumped PDL the matrix \(\text{U}\) is a staircase function in \(z\), hence, it is convenient breaking the integral in \(z\) into a summation of integrals between consecutive PDL elements, i.e., \(\int_0^z \rightarrow \sum_p \int_0^{z_p}
\)

With such substitutions we finally get:

\[
|\tilde{n}(\omega)| = -j \int_{-\infty}^{\infty} \sum_{p=0}^{N-1} \eta_p(\omega, \omega_1, \omega_2) \times

\langle \tilde{A}(\omega + \omega_1 + \omega_2) \text{P}(z_p) \tilde{A}(\omega + \omega_2) \rangle \frac{d\omega_1}{2\pi} \frac{d\omega_2}{2\pi}
\]

(26)

where \(\text{P}(z_p) \equiv \text{U}^\dagger(z_p) \text{U}(z_p)\) and \(\eta_p\) can be evaluated as per (25) but integrated over \((z_p, z_{p+1})\). If the source does not have PDL, we simply set \(\text{U}(z_0) = \text{I}\) at \(z = 0\).

### Appendix B

**Master Theorem**

The key ingredient to perform a statistical analysis is the variance of the NLI atom, i.e., \(\mathbb{E}[|n_1|^2]\):

\[
\mathbb{E}[|n_1|^2] = \sum a_k^* a_m a_n a_l a_1^* a_0^* \lambda_{kmmn} \lambda_{ljoi}^* .
\]

However, part of the NLI is compensated by digital signal-processing at the receiver. At the simplest level, a basic CPE removes the average phase \(\varphi\), which in the perturbative framework, corresponds to work with the following NLI:

\[
n_1^* = n_1 + j\varphi a_1 .
\]  

(27)

The real target is thus \(\mathbb{E}[|n_1^*|^2]\), which is given by the following:

**Theorem 1:** Assume all the \(a_k\) to be complex zero-mean independent random variables with \(n\)-fold rotational symmetry and \(n \geq 4\). Then:

\[
\mathbb{E}[|n_1^*|^2] = \sum_n \kappa_3^{(n)} |\lambda_{knmi}|^2

+ \sum_{k,n} \kappa_2^{(k)} \kappa_1^{(n)} \left( |\lambda_{kknk}|^2 + |\lambda_{nkki}|^2 \right)

+ \sum_{k,m,n} \kappa_1^{(k)} \kappa_1^{(m)} \lambda_{kmm} \lambda_{ljoi}^* (\lambda_{kmmn} + \lambda_{ljoi}^*)
\]  

(28)

with \(\kappa_n^{(k)}\) the \(n\)-th order cumulant of data symbols at channel use at time \(k_1\), frequency \(k_2\), and space \(k_3\).

Such a theorem is a generalization of the one provided in [19]. It is worth noting that the main difference is the broken degeneracy between the inner indexes of the tensor. For instance, the last term \(\lambda_{kmmn} + \lambda_{ljoi}^*\) is equal to \(2\lambda_{kmmn}^*\) in the scalar case according to (17). The basic intuition behind (28) is the following. Since the Kerr nonlinearity is cubic, the product \(n_1 n_1^*\) depends on the product of six atoms. Only combinations with an equal number of conjugate/non-conjugate pairs are non-zero, as depicted in Fig. 8. Each combination is weighted by the corresponding symbol-cumulant [19]. Please note that terms labeled with - in Fig. 8 correspond to the terms removed by the CPE in (27) [21].

The indexing of the valid combinations yields the terms in (28). Hence, for instance, the PDL-GN model reduces to the last triple summation in (28).

\[
\begin{array}{cccccc}
\hline
k^* & m & n & l & j^* & o^* \\
\hline
\bullet & \bullet & \bullet & \bullet & \bullet & Q6 \\
\bullet & \bullet & \circ & \bullet & \circ & F4 \\
\bullet & \circ & \bullet & \bullet & \circ & F4 \\
\bullet & \bullet & \bullet & \bullet & \bullet & - \\
\bullet & \bullet & \circ & \bullet & \circ & - \\
\bullet & \circ & \bullet & \circ & \bullet & - \\
\bullet & \bullet & \bullet & \bullet & \bullet & Q4 \\
\bullet & \bullet & \bullet & \circ & \circ & - \\
\bullet & \bullet & \circ & \circ & \circ & - \\
\bullet & \bullet & \circ & \circ & \circ & - \\
\bullet & \bullet & \bullet & \bullet & \bullet & GN \\
\bullet & \bullet & \bullet & \bullet & \bullet & GN \\
\hline
\end{array}
\]

Fig. 8. Valid combinations yielding non-zero \(\mathbb{E}[a_k^* a_m a_n a_l a_1^* a_0^*]\). For instance, the second row indicates the combination \(\{k = m = l = j\} \neq (n = o)\).

The labels indicate sixth-order noise (Q6), two types of fourth-order noise (F4 and Q4) and second-order noise, usually called GN contribution. A (-) indicates a phase contribution that is removed by the CPE.

Although the master theorem reduces the number of summations, the final result (28) still depends on an infinite summation over the discrete-time index. However, in the special case of sinc pulses, such a summation can be dropped, with significant simplifications, as already observed in [23], [20], thanks to the Poisson summation formula:

\[
\sum_{k=-\infty}^{\infty} e^{j\omega k T} = \frac{2\pi}{T} \sum_{k=-\infty}^{\infty} \delta \left( \omega - \frac{2\pi k}{T} \right)
\]  

(29)

and the finite bandwidth of the pulses that can interact with only one Dirac’s delta in such a summation. Instead of entering the fine mathematical details of the proof, the next theorem provides a short-rule for the simplifications:

**Theorem 2:** With sinc pulses \(p_h(t) = \text{sinc}(t/T)\), \(\forall h\), all summations in (28) over temporal indexes can be dropped. For each integral, an integral in the corresponding tensor-product \(\lambda_{kmm} \lambda_{ljoi}^*\) can be dropped as well. The dropped integral can be identified by solving a linear system obtained by equating the arguments \(\psi\) of the \(|G_k(\psi)|\) involved in the product owing to the same atom.

Such a result is best explained by an example. Let us focus on the particular GN-term \(G = \lambda_{kmm} \lambda_{ljoi}^*\) of (28) in the
scalar case. This term can be explicitly expanded following (13) as:

\[
G = \sum_{t, r=0}^{N-1} \int \int \int \int \int \eta_t(\omega, \omega_1, \omega_2) \eta_r^*(\mu, \mu_1, \mu_2) \\
\times \hat{G}_t^*(\omega + \omega_1 + \omega_2) \hat{G}_r^*(\omega + \omega_1 + \omega_2) \\
\times \hat{G}_m(\mu + \mu_1 + \mu_2) \hat{G}_n^*(\mu + \mu_1 + \mu_2) \\
\times \frac{d\omega_1}{2\pi} \frac{d\omega_2}{2\pi} \frac{d\mu_1}{2\pi} \frac{d\mu_2}{2\pi}.
\]

Equating the arguments of equal atoms yields the following linear system:

\[
\begin{align*}
\mathbf{k} & \rightarrow \omega + \omega_1 + \omega_2 = \mu_1 + \mu_2 + \mu \\
\mathbf{m} & \rightarrow \omega + \omega_2 = \mu + \mu_2 \\
\mathbf{n} & \rightarrow \omega + \omega_1 = \mu + \mu_1
\end{align*}
\]

whose solution is \( \omega_1 = \mu_1, \omega_2 = \mu_2, \omega = \mu \). We can thus drop three integrals, for instance the ones with \((\mu, \mu_1, \mu_2)_j\), by using the previous substitution.
