The discharge of industrial dyes and their breakdown products are often environmentally harmful. Here, we describe a biodegradation method using *Burkholderia multivorans* CCA53, which exhibits a capacity to degrade azo dyes, particularly ethyl red. Under the optimized culture conditions, 100 µM ethyl red was degraded more than 99% after incubation for 8 h. Real-time PCR analysis of *azoR1* and *azoR2*, encoding two azoreductases, revealed that transcription level of these genes is enhanced at early phase under the optimized conditions. For a more practical approach, hydrolysates were prepared from eucalyptus or Japanese cedar chips or rice straw, and rice straw hydrolysate was used as the best medium for ethyl red biodegradation. Under those conditions, ethyl red was also degraded with high efficiency (>91%). We have thus constructed a potentially economical method for the biodegradation of ethyl red.

**Key Words:** azoreductase; biodegradation; *Burkholderia multivorans*; ethyl red; hydrolysate; real time-PCR analysis

**Introduction**

A variety of dyes are used extensively to color textiles, foods, cosmetics, plastics, and numerous other consumer products. At present, more than 800,000 tons of dyes are produced annually worldwide. As a result of this widespread usage, there occurs a significant discharge of dyes into the natural environment, which is undesirable because the dyes and their breakdown products are often genotoxic, mutagenic, and/or carcinogenic in both animals (including humans) and plants. For example, Shinka et al. (1995) showed that the likelihood of cancerogenesis in factory workers is proportional to the duration of their dye exposure. Similar findings were reported for factory workers at a Chinese manufacturer (Bi et al., 1992), Italian dye-stuff workers (Piolatto et al., 1991), and Japanese kimono painters (Morikawa et al., 1997). In addition, factory workers showed a 12% higher mortality rate than the general population (Montanaro et al., 1997). Thus, it is necessary to degrade harmful dye products to harmless forms before discharging them into the natural environment.

The current treatment methods for degrading dye-contaminated waste are constructed based on chemical processes. For example, Fenton’s reagent is used to degrade both soluble and insoluble dyes (Pak and Chang, 1999). With photochemical methods, reactive oxygen species, including hydrogen peroxide and reactive radicals, are used to degrade dyes to CO₂ and H₂O (Oancea and Meltzer, 2014). In addition, physical processes are also useful for dye degradation. Membrane filtration can continuously separate most dyes from an effluent (Xu and Lebrun, 1999). Adsorption and ion exchange methods are very effective for removing both anionic and cationic dyes (Rafatullah et al., 2010). Although these methods have been applied in the textile industry, their costs are high and they require considerable energy consumption. Moreover, the byproducts of these reactions, which can include halides, metals, and/or chloride ions, are themselves toxic. For these reasons, microbial degradation has been studied for years to establish more effective and economical methods of degrading dyes. Several of the developed microbial methods have shown an ability to completely eliminate certain dyes. For example, textile dye waste containing reactive black RC, reactive yellow HF2-GL, reactive...
blue BGFN, reactive black B-150, and reactive red A-6BF can be decolorized using *Aspergillus fumigatus* XC6 (Jin et al., 2007). In addition, industrial effluent containing mainly scarlet RR is decolorized using a bacterial-yeast consortium with *Brevibacillus laterosporus* MTCC 2298 and *Galactomyces geotrichum* MTCC 1360 (Kurade et al., 2012). But although these methods show excellent decolorization rates, they require reagent-grade carbon, nitrogen, and mineral sources. For practical use, however, it would be preferable if that is unnecessary because reagent-grade materials are expensive.

*Burkholderia multivorans* species are currently being used as biocatalysts. For example, *B. multivorans* NG1 is used to degrade various aromatic polycyclic hydrocarbons, including naphthalene, *n*-hexadecane, *n*-octadecane, *n*-nonadecane, 1-methylnaphthalene and pyrene in liquids (Mohanty and Mukherji, 2013). In our previous study, *Burkholderia* sp. CCA53 was isolated from leaf soil (Akita et al., 2016b) and a draft genome sequence of this strain was determined (Akita et al., 2016a). Ultimately, the strain was identified as *B. multivorans* CCA53 based on its phylogenetic, phenotypic and biochemical characteristics (Akita et al., 2017). Notably, *B. multivorans* CCA53 exhibited a capacity for lignin degradation (Akita et al., 2016b). *B. multivorans* CCA53 is capable of growing on lignin as the sole carbon source, which entails cleavage of several main building blocks to assimilate lignin-associated aromatic monomers. Thus, we consider that *B. multivorans* CCA53 has a potential for dye degradation.

Here, we report the degradation of dyes using *B. multivorans* CCA53. After testing the degradation capacity of *B. multivorans* CCA53 with 13 kinds of dyes, the degradation of ethyl red was assessed. Moreover, real-time (RT)-PCR was performed to establish a correlation between ethyl red degradation and the transcription of azoreductase genes. As part of the development of practical applications, we also investigated the biodegradation of ethyl red using hydrolysate prepared from rice straw.

**Materials and Methods**

**Screening for dye-degradation capacity.** *B. multivorans* CCA53 was previously deposited in the HUT culture collection under strain number HUT-8135. Bordeaux S, bromothymol blue, congo red, cresol red, curcumin, ethyl red, fluorescein, methyl orange, methyl red, orange II, rhodamine B, thymol blue, and trypan blue were purchased from Fujifilm Wako Chemicals (Osaka, Japan) or Tokyo Chemical Industry (Tokyo, Japan). To confirm dye-degradation capacity, *B. multivorans* CCA53 was aerobiologically grown on LB plates (pH 7.0) containing 100 µM each dye for 3 days at 30°C.

**Optimization of the culture conditions for ethyl red degradation.** Ethyl red degradation was performed in a flask with a working volume of 20 mL. After *B. multivorans* CCA53 was pregrown overnight, the pre-culture was diluted to OD$_{600}$ = 0.05 with fresh LB medium containing 100 µM ethyl red, and then the culture was incubated under several conditions. The OD$_{600}$ was monitored over time.

| Primer    | Nucleotide sequence |
|-----------|---------------------|
| azoR1-fwd | 5’-GGCCGGCGATGTCACAATTCGTT-3’ |
| azoR1-rev | 5’-CTGAGAATGCTCAGGTCGGA-3’ |
| azoR2-fwd | 5’-TCTCATATGGATTGTACGCGG-3’ |
| azoR2-rev | 5’-ATCCAACGCTTGAAAGCTGAC-3’ |
| gyrB-fwd  | 5’-GAGTTCCTGCTGAAAGCGCC-3’ |

**Phylogenetic analysis of azoreductase.** Multiple alignment and construction of a neighbor-joining phylogenetic tree (Saitou and Nei, 1987) were performed using CLUSTAL W ver. 1.83 (Thompson et al., 1994) with the Tamura-Nei model (1993). All sequences were then compared with reference sequences available in the GenBank/EMBL/DDBJ databases using BLAST.
using a cutter mill (P-15; Fritsch Japan, Kanagawa, Japan), the resulting powders were separated into <3 mm particles by sieving. Thereafter, hydrothermal pretreatment was carried out according to the method of Fujimoto et al. (2018) with some modifications. The reaction mixture (50 mL) used for enzymatic saccharification contained 1 M acetate buffer (pH 5.0), 0.25 g/mL Acremonium cellulase (Meiji Seika Pharma, Tokyo, Japan), 0.20 g/mL Optimash BG (Genencor International, Rochester, NY, USA). After incubation for 72 h at 50°C, the reaction mixture was purified by filtration. The resulting solution was supplemented with corn steep liquor (Sigma-Aldrich, Saint Louis, MO, USA) to 1% of the final concentration and then used as the hydrolysate.

Quantification of sugars and other carbohydrates. After clarifying the culture by centrifugation and filtration, several kinds of sugars in the supernatant were quantified by HPLC (LC-10AD VP; Shimadzu, Kyoto, Japan) using an Aminex HPX-87H column (Bio-Rad Laboratories). The chromatographic conditions were as follows: mobile phase, ultrapure water; flow rate, 0.6 mL/min; and column oven temperature, 80°C. Sugar was detected using a refractive index indicator.

Furfural and 5-hydroxymethyl furfural were also analyzed by HPLC (LC-2000Plus; Jasco, Tokyo, Japan) using a Shodex SUGAR SH1821 column (Showa Denko, Tokyo, Japan). The chromatographic conditions were as follows: mobile phase, 2 mM H2SO4; flow rate, 0.6 mL/min; and column oven temperature, 60°C. These carbohydrates were also detected using a refractive index indicator.

Results and Discussion

Determination and optimization of the degradative capacity for ethyl red

To confirm its capacity to degrade dye, *B. multivorans* CCA53 was plated onto LB plates containing each tested dye. After incubation for 48 h at 30°C, decolorization of ethyl red was confirmed (Supplementary Fig. 1). Moreover, their decolorization proceeded with the time elapse. Decolorization of orange II, methyl red, and congo red was also confirmed after 72 h (data not shown). There was no decolorization of bordeaux S, bromothymol blue, cresol red, curcumin, fluorescein, methyl orange, rhodamine B, thymol blue, or trypan blue. These results demonstrated that *B. multivorans* CCA53 has the capacity to degrade mono azo dyes. Azo dye has one or more azo bonds (R1-N=N-R2), and contains a few linkages linking aromatic rings and/or functional groups. In the textile industry, more than 80% of the dyes used are azo dyes. Importantly, during the dyeing process, approximately 10% of azo dye does not bind to the fiber, and the unfixed dye is released into the natural environment (Asad et al., 2007). Thus, the establishment of an effective method for azo dye degradation is important.

We initially evaluated the effect of ethyl red concentrations (100–500 μM). Under the standard conditions, *B. multivorans* CCA53 was capable of growth in LB medium containing 100 μM ethyl red. However, a high concentration of ethyl red was unfavorable for the growth of *B. multivorans* CCA53, which was strongly inhibited by adding more than 200 μM ethyl red. Thus, we used 100 μM ethyl red for the degradation test. In our previous study, we found that the growth of *B. multivorans* CCA53 was affected by culture pH and temperature (Akita et al., 2017). Thus, the effects of culture pH and temperature for ethyl red degradation were evaluated. After *B. multivorans* CCA53 was incubated for 8 h, the maximum degradation efficiency was achieved at pH 7.5 (Fig. 1A). When the effect of culture temperature was investigated, the maximum degradation efficiency was obtained at 45°C (Fig. 1B). In conclusion, the optimized culture conditions for the degradation of ethyl red were a culture pH of 7.5 and a culture temperature of 45°C. Under the standard conditions, *B. multivorans* CCA53 decomposed 80% of ethyl red after incubation for 12 h, and the degradation efficiency reached >99% after incubation for 20 h (Fig. 2). Under the optimized conditions, by contrast, 84% of ethyl red was decomposed after incubation for 6 h, and the degradation efficiency was >99% after incubation for only 8 h (Fig. 2). The growth rate of *B. multivorans* CCA53 was also improved under the optimized culture conditions (Fig. 2). In contrast, the degradation of ethyl red did not occur...
Fig. 3. Relative transcription levels of azoR1 and azoR2 under the standard and optimized culture conditions.
Bars depict changes in the relative gene transcription at the indicated times without 100 µM ethyl red (white) or under the standard (light grey) and optimized (dark grey) culture conditions. Transcription levels are shown relative to that of gyrB, which served as an internal control. Error bars indicate SE (n = 3).

without *B. multivorans* CCA53.

The culture pH is especially important for industrial bacterial processes. Fungi and yeast exhibit high biodegradation activities at an acidic pH (Sen et al., 2016), but the degradation rate is lower at a neutral or an alkaline pH, which means that strict pH control is required to maintain effective culture conditions. By contrast, the activities of *B. multivorans* CCA53 were higher at pH 6.5–8.0, which is an advantage for practical utilization (Fig. 1). For ethyl red degradation using *B. multivorans* CCA53, we considered the culture temperature to be the most important factor. The maximum rate of dye degradation is generally related to the optimized culture temperature for each microbial species (Bardi and Marzona, 2010; Khan et al., 2013), but there were discrepancies with *B. multivorans* CCA53. For example, when *B. multivorans* CCA53 was cultured in Nutrient Broth without ethyl red, the maximum growth rate was achieved at 20°C (Akita et al., 2017). The reason for this was unclear, but we speculate that azoreductase activity is enhanced at that temperature. In fact, however, mesophilic bacterial azoreductases from *Bacillus* sp. B29 (Ooi et al., 2009), *Bacillus* sp. OY1-2 (Sugiura et al., 2006), and *Rhodococcus opacus* 1CP (Qi et al., 2016) exhibit maximum activity at 45–55°C. In the draft genome of *B. multivorans* CCA53, two azoreductase genes, designated azoR1 and azoR2, are annotated. The amino acid sequences of the two encoded enzymes show 36.7% identity. To confirm the relationships between the dye-degradation capacity of *B. multivorans* CCA53 and the transcription of each azoreductase gene, we next performed quantitative RT-PCR.

**Consideration on the degradative capacity of *B. multivorans* CCA53**

Microorganisms often accomplish dye biodegradation through the expression of several degradative enzymes. Actinomycete species are known to produce extracellular peroxidase, which catalyzes the removal of a hydrogen atom from the hydroxyl group of dyes (Sarkar et al., 2017). Laccase is mainly produced by white-rot fungi. This enzyme catalyzes the oxidation of various phenolic and aromatic compounds in the presence of molecular oxygen. Azoreductase catalyzes the reductive cleavage of azo bonds, which enables it to play an important role in bacterial dye degradation. Finally, those degradants are further degraded into simpler compounds (Stolz, 2001). Within the draft genome sequence of *B. multivorans* CCA53, two kinds of genes encoding azoreductase are confirmed. Thus, we next performed quantitative RT-PCR to investigate the transcription levels of azoR1 and azoR2 in *B. multivorans* CCA53 under the standard or optimized conditions (Fig. 3).

When *B. multivorans* CCA53 was cultured in LB medium without 100 µM ethyl red under the standard conditions, the transcription levels of azoR1 and azoR2 at 4–8 h were 1.5–2.5 and 0.38–0.40, respectively (Fig. 3). Under the standard conditions, the transcription levels of the two genes increased with the time in culture, and the highest transcription levels were detected after 12 h. Under the optimized conditions, transcription of azoR1 and azoR2 was enhanced at early phase, and their maximum levels were reached at 8 and 4 h, respectively. Although azoR1 was stably expressed under both conditions, the transcription level of azoR2 was clearly enhanced at early time under the optimized conditions. These results demonstrated that ethyl red adding induced the transcription level of azoR1 and azoR2, and the culture condition was effected by their transcription levels. This suggests that transcription mechanism of azoR1 and azoR2 may be similar to that of *B. multivorans* ATCC 17616 (Denman et al., 2014). When *B. multivorans* ATCC 17616 was cultured in mannitol-rich media, the transcription levels of genes related to sugar metabolism are also enhanced.

To further appraise the biodegradative capacity of *B. multivorans* CCA53, we constructed a neighbor-joining phylogenetic tree based on the amino acid sequences of several azoreductases (Fig. 4). Within the constructed tree, AzoR1 and AzoR2 from *B. multivorans* CCA53 showed a clear branching from close azoreductases. The sequence of *B. multivorans* CCA53 AzoR1 showed similarity to azoreductases from *Klebsiella pneumoniae* subsp. *pneumoniae* HS11286 (48.5%), *Shigella dysenteriae* SD197 (48.5%), *Pseudomonas aeruginosa* PA01 AzoR3 (46.9%) and *Escherichia coli* JM109 (46.8%). AzoR2 exhibited similarities of 44.3%, 43.1% and 42.7% its closest relatives from *Pantoea agglomerans* TX10, *Halomonas elongata* DSM 2581 and *Shewanella oneidensis* MR-1, respectively. The *P. agglomerans* enzyme shows the greatest specific activity toward methyl red (Moutaouakkil et al., 2003). More than 80% of its activity was detected at temperatures between 15 and 50°C or at pHs between 6.5 and 7.5. Similar characteristics were also observed with the azoreductase from *E. coli* (Cui et al., 2012). To determine the enzymatic characteristics of the azoR1 and azoR2 gene products, we are now planning to express each gene in recombinant *E. coli* cells. The results will be described elsewhere as the next stage of our study.

Overall, these results indicate that transcription of azoR1 and azoR2 was induced by the addition of ethyl red, and their transcription levels were markedly accelerated at early times under the optimized conditions. In addition to the greater transcription levels of azoR1 and azoR2, the
degradation activities of AzOR1 and AzOR2 may also be enhanced under the optimized conditions. Thus, the degradation efficiency of ethyl red was enhanced under the optimized conditions.

When ethyl red is degraded by azoreductase, anthranilate and \( \text{N, N-diethyl-1,4-phenylenediamine} \) are generated. Although \( B. \text{ce}p\text{a}c\text{i}a \) decomposes anthranilate to catechol by anthranilate 1,2-dioxygenase (Chang et al., 2003), this gene is not found in the draft genome sequence of \( B. \text{multivorans} \) CCA53 (Akita et al., 2016a). 

\( \text{N, N-diethyl-1,4-phenylenediamine} \), which has a similar structure to \( \text{N, N-diethyl-1,4-phenylenediamine} \), is demethylated to 1,4-phenylenediamine in azo dye-degrading bacteria (Yemashova and Kalyuzhnyi, 2006). However, 1,4-phenylenediamine is not further degraded and exists as an end product. These results suggest that \( B. \text{multivorans} \) CCA53 may lack the metabolic pathway for the complete degradation of ethyl red.

### Hydrolysate from lignocellulosic biomass

A broad range of assimilated carbon sources is a key characteristic of \( B. \text{multivorans} \) CCA53. When its carbon source utilization was characterized, it was found that \( B. \text{multivorans} \) CCA53 assimilates at least 27 different carbon sources (Akita et al., 2017). Tons of lignocellulosic biomass resources are generated every year in the agricultural and forest industries. Moreover, for example, fermentation of lignocellulosic biomass resources to bio-etha-
Each hydrolysate was prepared from lignocellulosic biomass: Eu, eucalyptus; Jc, Japanese cedar; Rs, rice straw. In fact, OD600 values were lower for the two hydrolysates prepared from eucalyptus and Japanese cedar chips as well as rice straw compared with the other two hydrolysates. Although glucose is the best carbon source for bacterial growth, high glucose concentrations inhibit their degradation efficiency and OD 600 were observed after incubation for 8 h, with consumption of >91% of the degradation efficiency was obtained with the eucalyptus hydrolysate (Table 2). We also confirmed the time-dependent changes in the degradation efficiency with hydrolysate from rice straw. We found that >91% of the degradation efficiency was achieved after incubation for 12 h, with consumption of 8.37 mM galactose, 5.24 mM glucose, 3.1 mM xylose, 1.53 mM arabinose and 0.64 mM mannose (Fig. 6 and Table 2).

**Ethyl red degradation using lignocellulosic hydrolysate**

When ethyl red degradation was performed, the highest degradation efficiency and OD600 were observed after incubation for 8 h with hydrolysate prepared from rice straw (Fig. 5). We consider the lower degradation efficiency seen with the other two hydrolysates was caused by the higher sugar concentration and the presence of aldehyde inhibitors. Although glucose is the best carbon source for bacterial growth, high glucose concentrations inhibit their growth (Kazana et al., 1995). In fact, OD600 values were reduced in the presence of higher glucose concentrations (Table 2). In addition, two aldehyde inhibitors, furfural, and 5-hydroxymethyl furfural, also inhibited bacterial growth. These compounds cause DNA damage and inhibit several enzymes in the glycolytic pathway, which leads to a decrease in cell growth (Monlau et al., 2014). When hydrolysates were prepared from each lignocellulosic biomass, furfural and 5-hydroxymethyl furfural were present only in the hydrolysate prepared from eucalyptus. This likely explains why the lowest degradation efficiency was obtained with the eucalyptus hydrolysate (Table 2). We found that >91% of the degradation efficiency was achieved after incubation for 12 h, with consumption of 8.37 mM galactose, 5.24 mM glucose, 3.1 mM xylose, 1.53 mM arabinose and 0.64 mM mannose (Fig. 6 and Table 2).

In the present study, we developed a potentially economical method for degrading ethyl red using *B. multivorans* CCA53. This method has several noteworthy features. First, the mesophilic bacterium *B. multivorans* CCA53 exhibits the highest activity at 45°C, and it requires no intricate culture conditions. These characteristics would be expected to decrease utility costs, even with large scale preparations. Second, *B. multivorans* CCA53 is capable of simultaneous assimilation of several carbon sources. Carbon catabolite repression, which leads to selective carbon-source usage, is seen with several industrially useful bacteria, including *Corynebacterium glutamicum* and *Escherichia coli* (Görke and Stülke, 2008). Release from carbon catabolite repression is needed to enhance productivity. It appears this carbon catabolite repression is weak in *B. multivorans* CCA53, which is advantageous for fermentation with lignocellulosic hydrolysate and may encourage the promotion of green sustainable chemistry. Third, *B. multivorans* CCA53 is not genetically modified. When using genetically modified bacteria in industry, it is necessary to follow the regulatory guidelines for recombinant DNA experiments, such as the...
Cartagena Protocol. These guidelines need not be applied to *B. multivorans* CCA53. On the other hand, a weakness of our method is the need to block the release of *B. multivorans* CCA53 into the atmosphere. Several *B. multivorans* species cause Cepacia syndrome in cystic fibrosis patients, which leads to pneumonic illness (Blackburn et al., 2004). With our method, therefore, a fermentation tank equipped with a high efficiency particulate air filter will be necessary to avoid infection by *B. multivorans* CCA53.

**Conclusion**

In this study, we have assessed ethyl red degradation using *B. multivorans* CCA53. This is the first report of an azo dye degradation method using a *B. multivorans* species. After investigating the effects of culture pH and temperature on ethyl red degradation, the optimized culture conditions were a culture pH of 7.5 and a culture temperature of 45°C. Under the optimized conditions, the efficiency of ethyl red degradation exceeded 99% after incubation for 8 h. Using quantitative RT-PCR and comparative sequence analysis, we investigated a correlation between ethyl red degradation and transcription of azoreductase genes. As the result, *B. multivorans* CCA53 would achieve its degradative capacity with two azoreductases, their activities may be enhanced under the optimized culture conditions. For a more practical approach, we performed ethyl red degradation using three kinds of hydrolysates as the medium. With hydrolysate fermentation tank equipped with a high efficiency catalytic oxidation.
