Abstract Chloroplast protrusions (CPs) have frequently been observed in plants, but their significance to plant metabolism remains largely unknown. We investigated in the alpine plant *Ranunculus glacialis* L. treated under various CO$_2$ concentrations if CP formation is related to photorespiration, specifically focusing on hydrogen peroxide (H$_2$O$_2$) metabolism. Immediately after exposure to different CO$_2$ concentrations, the formation of CPs in leaf mesophyll cells was assessed and correlated to catalase (CAT) and ascorbate peroxidase (APX) activities. Under natural irradiation, the relative proportion of chloroplasts with protrusions (rCP) was highest (58.7 %) after exposure to low CO$_2$ (38 ppm) and was lowest (3.0 %) at high CO$_2$ (10,000 ppm). The same relationship was found for CAT activity, which decreased from 34.7 nkat mg$^{-1}$ DW under low CO$_2$ to 18.4 nkat mg$^{-1}$ DW under high CO$_2$, while APX activity did not change significantly. When exposed to natural CO$_2$ concentration (380 ppm) in darkness, CP formation was significantly lower (18.2 %) compared to natural solar irradiation (41.3 %). In summary, CP formation and CAT activity are significantly increased under conditions that favour photorespiration, while in darkness or at high CO$_2$ concentration under light, CP formation is significantly lower, providing evidence for an association between CPs and photorespiration.

Introduction

Extensions of different organelles, including protrusions and stromules, are a frequently observed phenomenon (Gray et al. 2001; Hanson and Sattarzadeh 2008, 2011; Mathur et al. 2012), but their physiological functions remain largely unknown. In chloroplasts, different forms of stroma-filled extensions of the plastid envelope were described more than a century ago (e.g. Senn 1908; Heitz 1937; reviewed by Gray et al. 2001), referred to as protuberances and later as proliferations (Lütz and Moser 1977; Lütz 1987), stromules (Köhler and Hanson 2000) or chloroplast protrusions (Buchner et al. 2007a,b; Holzinger et al. 2007a,b). Stromules were described as long and thin stroma-filled tubules (diameter 0.4–0.8 μm, length up to 65 μm; Gray et al. 2001), similar to beak-like chloroplast protrusions (CPs) of the chloroplast envelope (diameter 3–5 μm, length 3–5 μm; Holzinger et al. 2007a) but significantly narrower. Both stromules and CPs may form and withdraw rapidly. For comprehensive literature concerning stromule activity and dynamics, see Köhler and Hanson (2000), Kwok and Hanson (2003, 2004a,b) and Hanson and Sattarzadeh (2008).

Stromules have been suggested to be involved in the protein trafficking (Köhler et al. 1997; Gray et al. 2001), and the mechanisms are currently being investigated (see Hanson and Sattarzadeh 2011, 2013; Schattat et al. 2012, 2015). Stromules differ from CPs in shape, and therefore, possibly in function. Moser et al. (2015) demonstrated that under natural
environmental conditions CP formation in leaves of *Ranunculus glacialis* follows a pronounced diurnal rhythm, and that CPs are most abundant in the afternoon and not related to temperature or irradiation stress. However, it has been suggested that CPs may contribute to the adaptation mechanisms of plants in extreme habitats such as in alpine and polar regions with short vegetation periods (Lütz and Engel 2007; Lütz 2010; Lütz et al. 2012).

Formation of CPs was shown to increase after acid mist treatment in Sitka spruce (Wulff et al. 1996) and in salt-stressed *Mesembryanthemum crystallinum* (Paramanova et al. 2004) and rice leaves, the latter of which contained crystalline inclusions within CPs alongside immunolabelled ribulose 1,5-bisphosphate carboxylase/oxygenase (rubisco) (Yamane et al. 2012). In early TEM studies on *R. glacialis* (Lütz 1987) and later in other high alpine and polar plant species (Gielwanowska and Szczuka 2005; Lütz et al. 2006; Holzinger et al. 2007b; Lütz and Engel 2007; Lütz 2010; Lütz et al. 2012), CPs were frequently found to be located in close spatial proximity to mitochondria and peroxisomes, suggesting a link between photorespiration and CP formation. However, quantitative evidence for this link is still missing. During photosynthesis, rubisco catalyses CO2 fixation; however, under increasing temperatures, rubisco increasingly reacts with O2 (photorespiration) and the resulting oxidation of ribulose-1,5-bisphosphate (RuBP) produces glycolate. This is broken down by glycolate oxidase in peroxisomes producing H2O2 which is detoxified by catalase (Mhamdi et al. 2012). Moser et al. (2015) found that CP formation was significantly reduced after exposure of *R. glacialis* to 2000 ppm CO2 and 2% O2, suggesting that a restriction of photorespiration, as achieved under these conditions, is involved in the withdrawal of CPs.

We used *R. glacialis* as a model alpine species to analyse the suggested link between photorespiration and CP formation in more detail. To achieve this, we measured CP formation in leaves exposed to solar irradiation at varying CO2 concentrations to favour or restrict photorespiration, and assessed the activity of catalase (CAT).

**Material and methods**

Plant material and study site

*R. glacialis* is one of the highest ascending (>4000 m a.s.l.) seed plants in the European Alps. As a pioneer species it prefers scree and humid siliceous substrates in the sub-nival and nival zone and is also present in arctic and subarctic regions (Schönswetter et al. 2003). Individuals of *R. glacialis* were carefully excavated near the Timmelsjoch pass (2563 m a.s.l.; Ötztal Alps, Tyrol, 46° 54′ N/11° 09′ E; 18 July 2013), potted and left in their natural habitat for 3 weeks.

The potted plants were transported to the ‘Alpine Garden Patscherkofel’ near Innsbruck (1950 m a.s.l.). For acclimation, the plants were partially shaded and carefully watered for 1 week until the experiments started on 15 August 2013.

**Exposure to different CO2 concentrations**

To determine the impact of different CO2 concentrations on CP formation under natural solar irradiation or darkness, four experimental conditions (ECs) were applied for 2.5 h. The CO2 concentrations in EC1 and EC2 were controlled to stimulate and prevent photorespiration, respectively. EC1 and EC2 comprised CO2 concentrations of 38 and 10,000 ppm, respectively, under natural solar irradiation. EC3 and EC4 comprised atmospheric CO2 concentrations (380 ppm) either kept in the dark using metal cylinders or under natural solar irradiation, respectively (Fig. 1a). Environmental conditions were maintained using highly transparent Plexiglas cylinders (200 × 350 mm, XT 29070, Röhm, Darmstadt, Germany; spectral transmittance: see Suppl. 1). Each cylinder contained five individuals of *R. glacialis* that were provided with variable CO2 concentrations (Airliquide, Schwechat, Austria) at a constant flow rate of 4000 ml min−1. Leaf temperatures of four individual leaves in EC1, EC2 and EC4 were monitored every 5 s by software-controlled heat tolerance testing system (HTTS; Buchner et al. 2013) to enable regulating EC3 to the same temperature of EC1, EC2 and EC4.

**Sampling and preservation**

At the end of a 2.5-h exposure, the chambers were quickly opened and leaf samples were taken (one per individual) and cut into 2×2 mm pieces that were fixed in 2.5% glutaraldehyde (GA) in sodium cacodylate buffer (50 mM, pH 7.0). After 1.5 h of immersion in the fixative, leaf pieces were rinsed with and subsequently stored in the same buffer at −80 °C and lyophilized (Lyovac GT 2, Leybold-Heraeus, Köln, Germany) for 5 days. Prior to chemical analysis, dry samples were ground (Tissue Lyser II, Qiagen, Venlo, the Netherlands) at a speed of 30 Hz for 2× 45 s and cooled with LN2.

**Numeric assessment of chloroplast protrusions**

Semi-thin sections (30 μm) were sliced from the GA-fixed leaf samples and analysed using an inverted microscope with differential interference contrast (DIC) optics (Axiovert 200 M; Plan-Apochromat 63×1.4 NA; Carl Zeiss, Jena, Germany). According to the method of Moser et al. (2015), the palisade parenchyma was photographed (Axiocam MCR 5, Carl Zeiss, Jena, Germany) and for each sample 10
individual cells were randomly selected. Stacks of images showing the same cell were analysed at different focal planes (Adobe Photoshop CS2, Adobe Systems Inc., San José, CA, USA). For each cell, 10 chloroplasts were thoroughly screened for CPs. Only chloroplasts positioned slightly off the cell wall, and not concealed by cell-wall fragments or other structures, were selected for further investigation. The relative proportion of chloroplasts with CPs (rCP) was calculated for each cell screened (1).

\[
rCP\% = 100\% \cdot \frac{n(CP)}{n}
\]

\[\text{n(CP)} \quad \text{number of chloroplasts showing at least one CP} \\
\text{n} \quad \text{number of chloroplasts inspected}
\]

Determination of enzyme activities

Sample preparation

Twenty milligrams of lyophilized and ground leafs were extracted in 1 ml 50 mM Sørensen’s buffer, pH 7, with 1 mM EDTA and vortexed for 15 s. The suspension was centrifuged at 4 °C for 5 min at 12,000 g and 600 μl of the supernatant was diluted with 1400 μl of extraction buffer. Enzymes were purified from low molecular weight compounds that interfered with enzyme assays with PD10 Sephadex® G-25 desalting columns (GE Healthcare, Chalfont St Giles, UK) with centrifugation (4 °C, 1000 g, 2 min). The resulting extract was kept on ice prior to measurements.

Catalase (CAT; 1.11.1.6) and ascorbate peroxidase (APX; EC 1.1.11.1) activities

CAT activity was measured by combining 100 μl of the extract with 620 μl of extraction buffer and 80 μl of 150 mM H2O2. The breakdown of H2O2 was measured by following the absorbance decrease at 240 nm (\(\varepsilon=43.6 \text{ M}^{-1} \text{ cm}^{-1}\)) for 2 min. APX activity was measured by combining 150 μl of extract with 820 μl extraction buffer, 20 μl of 10 mM ascorbate solution and 15 μl of 15 mM H2O2. The breakdown of ascorbate was measured by following the absorbance decrease at 265 nm (\(\varepsilon=7.0 \text{ mM}^{-1} \text{ cm}^{-1}\)) for 2 min. For CAT and APX activities, three technical replicates were measured for each biological replicate (\(n=5\)), and activity was normalized to dry mass.

Statistics

Correlation analysis and one-way ANOVA followed by related post hoc tests (Duncan, Games-Howell) to determine significant differences between means were calculated by statistical software (SPSS 21, IBM, Armonk, NY, USA).

Results

Leaf temperature and irradiation during the exposure phase

During the treatment, the photosynthetically active photon flux density (PPFD) varied from 360 to 967 μmol photons m\(^{-2}\) s\(^{-1}\) (mean 715), which is below the maxima that may occur in the field (>2500 μmol photons m\(^{-2}\) s\(^{-1}\)) but in the range of mean PPFD during daytime (Buchner, unpublished
data). Leaf temperatures of the four different ECs were around 36 °C and almost identical (Table 1) and never fell below 31 °C (Fig. 1b), whereas short leaf temperature maxima up to 41.9 °C occurred. At natural growing sites of *R. glacialis* mean leaf temperatures during daytime are typically lower, but maximum half hourly mean values around 37–38 °C occur occasionally (Buchner et al. 2015; Moser et al. 2015) and do not cause any leaf damage (Larcher et al. 1997; Buchner et al. 2015). Even short exposure to 41.9 °C as applied here does not induce lethal leaf damage (Buchner et al. 2015), but it stimulates photorespiration because the specificity of rubisco to CO₂ over O₂ is reduced as is the solubility of CO₂ (Brooks et al. 1985).

Impact of CO₂ concentration on the formation of CPs

In DIC images, CPs were easily identifiable as broad, stroma-filled lobes (Fig. 1c, d). Although CPs were present in all ECs, they were most abundant (mean±SE) after exposure to light under 38 ppm CO₂ (58.7±4.6). In contrast, rCP was lowest after exposure to light under 10,000 ppm CO₂ (3.0±0.7). Exposure to solar irradiation at the natural ambient CO₂ concentration (380 ppm) led to an rCP of 41.3±4.4, while the same treatment in the dark led to an rCP of 18.2±4.2. Mean values of rCP differed significantly (*P*<0.05) between all ECs (Fig. 2a).

Impact of CO₂ concentration on CAT and APX activities

CAT activity was significantly higher (*P*<0.05) after light exposure under 38 ppm CO₂ (34.7 nkat mg⁻¹ DW±1.8) compared to light exposure under 10,000 ppm CO₂ (18.4 nkat mg⁻¹ DW±1.5). Exposure to natural CO₂ concentrations (380 ppm) resulted in an enzyme activity of 22.2 nkat mg⁻¹ DW±3.2 in the light and 20.4 nkat mg⁻¹ DW±2.6 in darkness (Fig. 2b). Results of EC2, EC3 and EC4 did not differ significantly from each other (*P*>0.05). No significant differences were found for APX activity between the four ECs. An overview of rCP, CAT and APX activities subsequent to the exposure to the different ECs is given in Table 1.

| Experimental condition [EC] | CO₂ [ppm] | PPFD [μmol photons m⁻² s⁻¹] | TL [°C] | rCP [%] | CAT [nkat mg⁻¹ DW] | APX [nkat mg⁻¹ DW] |
|-----------------------------|-----------|---------------------------|--------|--------|-------------------|------------------|
| EC 1                        | 38        | 715                       | 35.9/39.2 | 58.7   | 34.7              | 0.34             |
| EC 2                        | 10,000    | 715                       | 35.9/39.8 | 3.0    | 18.4              | 0.27             |
| EC 3                        | 380       | 0                         | 36.3/41.9 | 18.2   | 20.4              | 0.29             |
| EC 4                        | 380       | 715                       | 36.6/41.0 | 41.3   | 22.2              | 0.31             |

$rCP$ and CAT activities in relation to CO₂/O₂ ratio

The CO₂/O₂ ratio significantly affected CP formation and CAT activity. In the light (EC1, EC2, EC4), rCP and CAT activities significantly (*P*=0.001) correlated negatively with the CO₂/O₂ ratio (Spearman’s *r*ho=−0.756 and −0.771, respectively) (Fig. 2c). Furthermore, rCP and CAT activities were positively correlated (Spearman’s *r*ho=0.666, *P*=0.011). However, no correlations were found between APX activity and the CO₂/O₂ ratio or rCP (data not shown).

Discussion

Photorespiration and CP formation

It is believed that photorespiration requires close spatial proximity of chloroplasts, peroxisomes and mitochondria to allow transport of metabolites between these organelles (Douce and Neuburger 1999; Eisenhut et al. 2013). It has been suggested that the formation of CPs supports photorespiration by bridging gaps between organelles (Lütz et al. 2012; Hanson and Sattarzadeh 2011) and by enlarging the chloroplast surface to facilitate envelope-bound transport (Lütz 1987; Lütz 2010; Holzinger et al. 2007b; Lütz and Engel 2007). Furthermore, Sage and Sage (2009) suggested that CPs (or stromules) may also operate as a photosynthetic CO₂-scavenging system that supports re-fixation of photorespiratory-released CO₂. Catalase, which is essential in scavenging H₂O₂ produced from photorespiration, is almost exclusively located in peroxisomes and also plays a role in stress response (Feierabend 2005; Wingler et al. 2000; Mhamdi et al. 2012). Accumulation of H₂O₂ was shown to occur in microbodies of *R. glacialis* using diaminobenzidine (Lütz 1987), which is a stain commonly used for H₂O₂ in relation to peroxidase activity (e.g. Roach et al. 2010). However, it was not known if CAT activity was related to CP formation.

Hydrogen peroxide can be scavenged by several enzymes, including CAT and peroxidases. APX plays a key role in the ascorbate-glutathione cycle, which serves to scavenge H₂O₂ (Foyer and Noctor 2011). However, only CAT activity but not...
APX activity correlated with CP formation, which suggests that there was a need for enhanced H$_2$O$_2$ scavenging in peroxisomes rather than chloroplasts. Interestingly, this indicates that the low CO$_2$ treatment used to promote photorespiration apparently did not induce the Mehler reaction, agreeing with a recent rethinking that the Mehler reaction is restricted under low CO$_2$ conditions (Noctor et al. 2014; Roach et al. 2015). The exposure to varying CO$_2$/O$_2$ ratios allowed us to modulate photorespiration, showing that CP formation positively correlates with CAT activity (Fig. 2a, b), supporting the hypothesis that CP formation and photorespiration are linked, although a causal relationship is still to be confirmed. Furthermore, it will be interesting to study if organelle extensions such as stromules and CPs also support signalling pathways (Noctor et al. 2007), such as retrograde signalling, which is essential for coordinating cellular activities during plant stress response (Kwok and Hanson 2004a; Fernández and Strand 2008).

Chloroplast protrusions—a multifaceted phenomenon

Chloroplast protrusions are not solely formed during photorespiration, but also seem to have other roles. We show that CPs were also formed under conditions that do not induce photorespiration (Fig. 2a). If the only role of CPs was in photorespiration, no CPs would be formed in the dark. However, rCP was not zero after exposure to 380 ppm CO$_2$ in darkness. In *R. glacialis*, Moser et al. (2015) observed highest rCP values at moderately solar irradiation and moderately elevated leaf temperatures with a significant correlation between leaf temperature and rCP. Furthermore, rCP at 50 ppm did not differ significantly from that at 370 ppm CO$_2$, indicating that photorespiration was not the main reason for CP formation, because leaf temperature was only 25 °C (compared to ~36 °C used here). In *Arabidopsis*, CP formation increased with temperature, likely supporting the increased transport of metabolites required for increased metabolic rates at high temperature (Holzinger et al. 2007a). Even in darkness CP formation apparently may support metabolite transport out of the chloroplast during the degradation of transitory starch (Schleucher et al. 1998).

Recent results indicate that increased CP formation could also be related to stress factors. Our results and those of Moser et al. (2015) do not strongly indicate that CPs are formed in response to temperature and irradiation stress. On the other hand, in rice (Yamane et al. 2012) and soybean (He et al. 2014), high salt concentration promoted the formation of CPs and rubisco-containing bodies. In wheat seedlings, protrusions of the chloroplast envelope were shown to be increased during water stress (Freeman and Duysen 1975). Chloroplast swelling and the occurrence of large thylakoid-free areas have also been described in context with chilling or sublethal freezing (Ciamporová and Trginová 1999; Stefanowska et al. 2002) or after heat stress (Larcher et al. 1997). Furthermore, Ishida et al. (2014) showed that vesicles originating from stromules or CPs may be involved in autophagic processes in context with nutrient recycling and chloroplast function maintenance.
In summary, this short communication shows a strong correlation between CP formation and CAT activity, in support of the hypothesis that photosrespiration is linked with CP formation, and that CP formation is a multifaceted phenomenon with more than one physiological role.
