Abstract

Consider the problem of minimizing the sum of a smooth (possibly non-convex) and a convex (possibly nonsmooth) function involving a large number of variables. A popular approach to solve this problem is the block coordinate descent (BCD) method whereby at each iteration only one variable block is updated while the remaining variables are held fixed. With the recent advances in the developments of the multi-core parallel processing technology, it is desirable to parallelize the BCD method by allowing multiple blocks to be updated simultaneously at each iteration of the algorithm. In this work, we propose an inexact parallel BCD approach where at each iteration, a subset of the variables is updated in parallel by minimizing convex approximations of the original objective function. We investigate the convergence of this parallel BCD method for both randomized and cyclic variable selection rules. We analyze the asymptotic and non-asymptotic convergence behavior of the algorithm for both convex and non-convex objective functions. The numerical experiments suggest that for a special case of Lasso minimization problem, the cyclic block selection rule can outperform the randomized rule.

1 Introduction

Consider the following optimization problem

\[
\min_x \ h(x) \triangleq f(x_1, \ldots, x_n) + \sum_{i=1}^n g_i(x_i) \ \text{s.t.} \ x_i \in X_i, \ i = 1, 2, \ldots, n,
\]

where $X_i \subseteq \mathbb{R}^{m_i}$ is a closed convex set; the function $f : \prod_{i=1}^n X_i \to \mathbb{R}$ is a smooth function (possibly non-convex); and $g(x) \triangleq \sum_{i=1}^n g_i(x_i)$ is a separable convex function (possibly nonsmooth). The above optimization problem appears in various fields such as machine learning, signal processing, wireless communication, image processing, social networks, and bioinformatics, to name just a few. These optimization problems are typically of huge size and should be solved expeditiously.

A popular approach for solving the above multi-block optimization problem is the block coordinate descent (BCD) approach, where at each iteration of BCD, only one of the block variables is updated, while the remaining blocks are held fixed. Since only one block is updated at each iteration, the per-iteration storage and computational demand of the algorithm is low, which is desirable in huge-size problems. Furthermore, as observed in [1–3], these methods perform particularly well in practice.

The availability of high performance multi-core computing platforms makes it increasingly desirable to develop parallel optimization methods. One category of such parallelizable methods is the (proximal) gradient methods. These methods are parallelizable in nature [4–8]; however, they are
equivalent to successive minimization of a quadratic approximation of the objective function which
can be tight; and hence suffer from low convergence speed in some practical applications [9].

To take advantage of the BCD method and parallel multi-core technology, different parallel BCD
algorithms have been recently proposed in the literature. In particular, the references [10][12] propose
parallel coordinate descent minimization methods for \( \ell_1 \)-regularized convex optimization problems.
Using the greedy (Gauss-Southwell) update rule, the recent works [9][13] propose parallel BCD type
methods for general composite optimization problems. In contrast, references [2][14][20] suggest
randomized block selection rule, which is more amenable to big data optimization problems, in
order to parallelize the BCD method.

Motivated by [1][9][15][21], we propose a parallel inexact BCD method where at each iteration of the
algorithm, a subset of the blocks is updated by minimizing locally tight approximations of the objective
function. Asymptotic and non-asymptotic convergence analysis of the algorithm is presented in
both convex and non-convex cases for different variable block selection rules. The proposed parallel
algorithm is synchronous, which is different than the existing lock-free methods in [22][23].

The contributions of this work are as follows:

- A parallel block coordinate descent method is proposed for non-convex nonsmooth problems. To the best of our knowledge, reference [9] is the only paper in the literature that focuses on parallelizing BCD for non-convex nonsmooth problems. This reference utilizes greedy block selection rule which requires exhaustive search among all blocks as well as communication among processing nodes in order to find the best blocks to update. This requirement can be demanding in practical scenarios where the communication among nodes are costly or when the number of blocks is huge.

- The proposed parallel BCD algorithm allows both cyclic and randomized block variable
  selection rules. The deterministic (cyclic) update rule is different than the existing parallel randomized or greedy BCD methods in the literature; see, e.g., [2][9][13][20]. Based on our numerical experiments, this update rule is beneficial in solving the Lasso problem.

- The proposed method not only works with the constant step-size selection rule, but also
  with the diminishing step-sizes which is desirable when the Lipschitz constant of the objective
  function is not known.

- Unlike many existing algorithms in the literature, e.g., [13][15], our parallel BCD algorithm
  utilizes the general approximation of the original function which includes the linear/proximal approximation of the objective as a special case. The use of general approximation instead of the linear/proximal approximation offers more flexibility and results in efficient algorithms for particular practical problems; see [2][24] for specific examples.

- We present an iteration complexity analysis of the algorithm for both convex and non-
  convex scenarios. Unlike the existing non-convex parallel methods in the literature such as [9] which only guarantee the asymptotic behavior of the algorithm, we provide non-
  asymptotic guarantees on the convergence of the algorithm as well.

2 Parallel Successive Convex Approximation

As stated in the introduction section, a popular approach for solving (1) is the BCD method where at
iteration \( r+1 \) of the algorithm, the block variable \( x_i \) is updated by solving the following subproblem
\[
    x_i^{r+1} = \arg \min_{x_i \in X_i} h(x_1^{r}, \ldots, x_{i-1}^{r}, x_i, x_{i+1}^{r}, \ldots, x_n^{r}).
\]
(2)

In many practical problems, the update rule (4) is not in closed form and hence not computationally
cheap. One popular approach is to replace the function \( h(\cdot) \) with a well-chosen local convex
approximation \( \tilde{h}_i(x_i, x^r) \) in (2). That is, at iteration \( r+1 \), the block variable \( x_i \) is updated by
\[
    x_i^{r+1} = \arg \min_{x_i \in X_i} \tilde{h}_i(x_i, x^r),
\]
(3)

where \( \tilde{h}_i(x_i, x^r) \) is a convex (possibly upper-bound) approximation of the function \( h(\cdot) \) with respect to the \( i \)-th block around the current iteration \( x^r \). This approach, also known as block successive
convex approximation or block successive upper-bound minimization [21], has been widely used in
different applications; see [21] for more details and different useful approximation functions. In this work, we assume that the approximation function \( \tilde{h}_i(\cdot, \cdot) \) is of the following form:

\[
\tilde{h}_i(x_i, y) = \tilde{f}_i(x_i, y) + g_i(x_i).
\]

Here \( \tilde{f}_i(\cdot, y) \) is an approximation of the function \( f(\cdot) \) around the point \( y \) with respect to the \( i \)-th block. We further assume that \( \tilde{f}_i(x_i, y) : \mathcal{X}_i \times \mathcal{X} \rightarrow \mathbb{R} \) satisfies the following assumptions:

- \( \tilde{f}_i(\cdot, y) \) is continuously differentiable and uniformly strongly convex with parameter \( \tau \), i.e.,
  \[
  \tilde{f}_i(x_i, y) \geq \tilde{f}_i(x'_i, y) + \langle \nabla_{x_i} \tilde{f}_i(x'_i, y), x_i - x'_i \rangle + \frac{\tau}{2} \| x_i - x'_i \|^2, \quad \forall x_i, x'_i \in \mathcal{X}_i, \quad \forall y \in \mathcal{X}.
  \]

- **Gradient consistency assumption:** \( \nabla_{x_i} \tilde{f}_i(x_i, x) = \nabla_x f(x), \quad \forall x \in \mathcal{X} \)

- \( \nabla_{x_i} \tilde{f}_i(x_i, \cdot) \) is Lipschitz continuous on \( \mathcal{X} \) for all \( x_i \in \mathcal{X}_i \) with constant \( \tilde{L} \), i.e.,
  \[
  \| \nabla_{x_i} \tilde{f}_i(x_i, y) - \nabla_{x_i} \tilde{f}_i(x_i, z) \| \leq \tilde{L} \| y - z \|, \quad \forall y, z \in \mathcal{X}, \quad \forall x_i \in \mathcal{X}_i, \quad \forall i.
  \]

For instance, the following traditional proximal/quadratic approximations of \( f(\cdot) \) satisfy the above assumptions when the feasible set is compact and \( f(\cdot) \) is twice continuously differentiable:

- \( \tilde{f}(x_i, y) = \langle \nabla_y f(y), x_i - y_i \rangle + \frac{\alpha}{2} \| x_i - y_i \|^2 \).
- \( \tilde{f}(x_i, y) = f(x_i, y_i) + \frac{\alpha}{2} \| x_i - y_i \|^2 \), for \( \alpha \) large enough.

To see other practical useful approximations of \( f(\cdot) \), see [21].

With the recent advances in the development of parallel processing machines, it is desirable to take the advantage of multi-core machines by updating multiple blocks simultaneously in (3). Unfortunately, naively updating multiple blocks simultaneously using the approach in (3) does not result in a convergent algorithm. Hence, we suggest to modify the update rule by using a well-chosen step-size. More precisely, we propose Algorithm 1 for solving the optimization problem (1).

**Algorithm 1 Parallel Successive Convex Approximation (PSCA) Algorithm**

\[
\text{find a feasible point } x^0 \in \mathcal{X} \text{ and set } r = 0
\]
\[
\text{for } r = 0, 1, 2, \ldots \text{ do}
\]
\[
\quad \text{choose a subset } S^r \subseteq \{1, \ldots, n\}
\]
\[
\quad \text{calculate } \tilde{x}^r_i = \arg \min_{x_i \in \mathcal{X}_i} \tilde{h}_i(x_i, x^r), \quad \forall i \in S^r
\]
\[
\quad \text{set } x^{r+1}_i = x^r_i + \gamma^r (\tilde{x}^r_i - x^r_i), \quad \forall i \in S^r, \quad \text{and set } x^{r+1}_i = x^r_i, \quad \forall i \notin S^r
\]
\[
\text{end for}
\]

The procedure of selecting the subset \( S^r \) is intentionally left unspecified in Algorithm 1. This selection could be based on different rules. Reference [9] suggests the greedy variable selection rule where at each iteration of the algorithm in [9], the best response of all the variables are calculated and at the end, only the block variables with the largest amount of improvement are updated. A drawback of this approach is the overhead caused by the calculation of all of the best responses at each iteration; this overhead is especially computationally demanding when the size of the problem is huge. In contrast to [9], we suggest the following randomized or cyclic variable selection rules:

- **Cyclic:** Given the partition \( \{T_0, \ldots, T_{m-1}\} \) of the set \( \{1, 2, \ldots, n\} \) with \( T_i \cap T_j = \emptyset, \quad \forall i \neq j \) and \( \bigcup_{\ell=0}^{m-1} T_\ell = \{1, 2, \ldots, n\} \), we say the choice of the variable selection is cyclic if
  \[
  S^{m \ell + r} = T_\ell, \quad \forall \ell = 0, 1, \ldots, m - 1 \text{ and } r,
  \]

- **Randomized:** The variable selection rule is called randomized if at each iteration the variables are chosen randomly and independently from the previous iterations so that
  \[
  Pr (j \in S^r \mid x^r) = p^r_j \geq p_{\text{min}} > 0, \quad \forall j = 1, 2, \ldots, n, \quad \forall r.
  \]

### 3 Convergence Analysis: Asymptotic Behavior

We first make a standard assumption that \( \nabla f(\cdot) \) is Lipschitz continuous with constant \( L_{\nabla f} \), i.e.,

\[
\| \nabla f(x) - \nabla f(y) \| \leq L_{\nabla f} \| x - y \|.\]
Let us also define $\tilde{x}$ to be a stationary point of (1) if $\exists \mathbf{d} \in \partial g(\tilde{x})$ such that $(\nabla f(\tilde{x}) + d, x - \tilde{x}) \geq 0$, $\forall x \in \mathcal{X}$, i.e., the first order optimality condition is satisfied at the point $\tilde{x}$. The following lemma will help us to study the asymptotic convergence of the PSCA algorithm.

**Lemma 1** [9] **Lemma 2** Define the mapping $\tilde{x}(\cdot) : \mathcal{X} \rightarrow \mathcal{X}$ as $\tilde{x}(y) = (\tilde{x}_i(y))_{i=1}^{n}$ with $\tilde{x}_i(y) = \arg \min_{x_i \in \mathcal{X}} h_i(x_i, y)$. Then the mapping $\tilde{x}(\cdot)$ is Lipschitz continuous with constant $\tilde{L} = \sqrt{\frac{\gamma}{r}}$, i.e.,

$$\|\tilde{x}(y) - \tilde{x}(z)\| \leq \tilde{L}\|y - z\|, \ \forall y, z \in \mathcal{X}.$$ 

Having derived the above result, we are now ready to state our first result which studies the limiting behavior of the PSCA algorithm. This result is based on the sufficient decrease of the objective function which has been also exploited in [9] for greedy variable selection rule.

**Theorem 1** Assume $\gamma^r \in (0, 1]$, $\sum_{r=1}^{\infty} \gamma^r = +\infty$, and that $\lim \sup_{r \rightarrow \infty} \gamma^r < \bar{\gamma} \triangleq \min\{\frac{r^\beta}{r^\alpha}, r \rightarrow \infty\}$. Suppose either cyclic or randomized block selection rule is employed. For cyclic update rule, assume further that $\{\gamma^r\}_{r=1}^{\infty}$ is a monotonically decreasing sequence. Then every limit point of the iterates is a stationary point of (1) — deterministically for cyclic update rule and almost surely for randomized block selection rule.

**Proof** Let us first show the result for the randomized block selection rule. We will do so by proving that $\lim_{r \rightarrow \infty} \|\tilde{x}^r - x^r\| = 0$, with probability one. To show this, we start by bounding the decrease in the objective value in the consecutive steps of the algorithm:

$$h(x^{r+1}) = f(x^{r+1}) + \sum_i g_i(x_i^{r+1}) = f(x^{r+1}) + \sum_{i \in S^r} g_i(x_i^{r}) + \sum_{i \in S^r} g_i(x_i^{r} + \gamma^r(\tilde{x}_i^r - x_i^{r}))$$

$$\leq f(x^{r+1}) + \sum_{i \in S^r} g_i(x_i^{r}) + \gamma^r \sum_{i \in S^r} (g_i(\tilde{x}_i^r) - g_i(x_i^{r}))$$

$$\leq f(x^{r}) + \gamma^r (\nabla f(x^{r}), \tilde{x}^r - x^{r})_{S^r} + \frac{(\gamma^r)^2 L_{\nabla f}}{2} \|\tilde{x}^r - x^{r}\|_{S^r}^2 + \sum_{i \in S^r} g_i(x_i^{r}) + \gamma^r \sum_{i \in S^r} (g_i(\tilde{x}_i^r) - g_i(x_i^{r}))$$

$$= h(x^{r}) + \frac{(\gamma^r)^2 L_{\nabla f}}{2} \|\tilde{x}^r - x^{r}\|_{S^r}^2 + \gamma^r \left(\langle \nabla f(x^{r}), \tilde{x}^r - x^{r}\rangle_{S^r} + \sum_{i \in S^r} (g_i(\tilde{x}_i^r) - g_i(x_i^{r}))\right),$$

where the first inequality is due to convexity of $g(\cdot)$; the second inequality is due to the Lipschitz continuity of $\nabla f(\cdot)$; and we have also used the notation $\langle a, b \rangle_s \triangleq \sum_{i \in S} \langle a_i, b_i \rangle$ and $\|a\|_S \triangleq \langle a, a \rangle_s$. In order to get a standard form sufficient decrease bound, we need to bound the last term in (5). Noticing that $h_i$ is strongly convex, the definition of $\tilde{x}_i^r$ leads to

$$\tilde{h}_i(x_i^{r}, x^{r}) \geq \tilde{h}_i(\tilde{x}_i^r, x^{r}) + \frac{T}{2} \|\tilde{x}_i^r - x_i^{r}\|^2, \ \forall i \in S^r.$$ 

Substituting the definition of $\tilde{h}_i$ and multiplying both sides by minus one give

$$-\tilde{f}_i(x_i^{r}, x^{r}) - g_i(x_i^{r}) \leq -\tilde{f}_i(\tilde{x}_i^r, x^{r}) - g_i(\tilde{x}_i^r) - \frac{T}{2} \|\tilde{x}_i^r - x_i^{r}\|^2.$$ 

Linearizing the smooth part, the gradient consistency assumption leads to

$$\langle \nabla f(x^{r}), \tilde{x}_i^r - x_i^{r} \rangle + g_i(\tilde{x}_i^r) - g_i(x_i^{r}) \leq -\frac{T}{2} \|\tilde{x}_i^r - x_i^{r}\|^2.$$ 

Summing up the above inequality over all $i \in S^r$, we obtain

$$\langle \nabla f(x^{r}), \tilde{x}^r - x^{r}\rangle_{S^r} + \sum_{i \in S^r} \langle g_i(\tilde{x}_i^r) - g_i(x_i^{r}) \rangle \leq -\frac{T}{2} \|\tilde{x}^r - x^{r}\|_{S^r}^2,$$ 

where $\tilde{x}^r \triangleq (\tilde{x}_i^r)_{i=1}^{n}$. Combining (5) and (6) leads to

$$h(x^{r+1}) \leq h(x^{r}) + \frac{\gamma^r(-T + \gamma^r L_{\nabla f})}{2} \|\tilde{x}^r - x^{r}\|_{S^r}^2.$$ 

Since $\lim \sup_{r \rightarrow \infty} \gamma^r < \bar{\gamma}$, for sufficiently large $r$, there exists $\beta > 0$ such that

$$h(x^{r+1}) \leq h(x^{r}) - \beta \gamma^r \|\tilde{x}^r - x^{r}\|_{S^r}^2.$$ 

(7)
Taking the conditional expectation from both sides implies
\[
E[h(x^{r+1}) | x^r] \leq h(x^r) - \beta \gamma^r \mathbb{E} \sum_{i=1}^{n} R^r_i \| \bar{x}_i^r - x_i^r \|^2 | x^r],
\]
(8)
where \( R^r_i \) is a Bernoulli random variable which is one if \( i \in S^r \) and it is zero otherwise. Clearly, \( \mathbb{E}[R^r_i | x^r] = p^r_i \) and therefore,
\[
E[h(x^{r+1}) | x^r] \leq h(x^r) - \beta \gamma^r p^{r}_{\min} \| \bar{x}^r - x^r \|^2, \quad \forall r.
\]
(9)
Thus \( \{h(x^r)\} \) is a supermartingale with respect to the natural history; and by the supermartingale convergence theorem [25] Proposition 4.2, \( h(x^r) \) converges and we have
\[
\sum_{r=1}^{\infty} \gamma^r \| \bar{x}^r - x^r \|^2 < \infty, \quad \text{almost surely.}
\]
(10)
Let us now restrict our analysis to the set of probability one for which \( h(x^r) \) converges and \( \sum_{r=1}^{\infty} \gamma^r \| \bar{x}^r - x^r \|^2 < \infty \). Fix a realization in that set. The equation (10) simply implies that, for the fixed realization, \( \liminf_{r \rightarrow \infty} \| \bar{x}^r - x^r \| = 0 \). Now we strengthen this result by proving that \( \lim_{r \rightarrow \infty} \| \bar{x}^r - x^r \| = 0 \). Suppose the contrary that there exists \( \delta > 0 \) such that \( \Delta^r \geq \delta \) \( \| \bar{x}^r - x^r \| \geq 2 \delta \) infinitely often. Since \( \liminf_{r \rightarrow \infty} \Delta^r = 0 \), there exists a subset of indices \( K \) and \( \{i_r\} \) such that for any \( r \in K \),
\[
\Delta^r < \delta, \quad 2 \delta < \Delta^r, \quad \text{and} \quad \delta \leq \Delta^r \leq 2 \delta, \quad \forall j = r + 1, \ldots, i_r - 1.
\]
(11)
Clearly,
\[
\delta - \Delta^r \leq \Delta^{r+1} - \Delta^r = \| \bar{x}^{r+1} - x^{r+1} \| - \| \bar{x}^r - x^r \| \leq \| \bar{x}^{r+1} - \bar{x}^r \| + \| x^{r+1} - x^r \|
\]
(12)
where (i) and (ii) are due to (11) and (ii) is followed from the algorithm iteration update rule. Since \( \limsup_{r \rightarrow \infty} \gamma^r < \frac{1}{1 + \delta} \), the above inequality implies that there exists an \( \alpha > 0 \) such that
\[
\Delta^r > \alpha,
\]
(13)
for all \( r \) large enough. Furthermore, since the chosen realization satisfies (10), we have that \( \lim_{r \rightarrow \infty} \sum_{t=r}^{i_r-1} \gamma^t (\Delta^t)^2 = 0 \); which combined with (11) and (13), implies
\[
\lim_{r \rightarrow \infty} \sum_{t=r}^{i_r-1} \gamma^t = 0.
\]
(14)
On the other hand, using the similar reasoning as in above, one can write
\[
\delta < \Delta^r - \delta^r = \| \bar{x}^r - x^r \| - \| \bar{x}^r - x^r \| \leq \| \bar{x}^r - \bar{x}^r \| + \| x^r - x^r \|
\]
\[
\leq (1 + \hat{L}) \sum_{t=r}^{i_r-1} \gamma^t \| \bar{x}^r - x^r \| \leq 2 \delta (1 + \hat{L}) \sum_{t=r}^{i_r-1} \gamma^t,
\]
and hence \( \liminf_{r \rightarrow \infty} \sum_{t=r}^{i_r-1} \gamma^t > 0 \), which contradicts (14). Therefore the contrary assumption does not hold and we must have \( \lim_{r \rightarrow \infty} \| \bar{x}^r - x^r \| = 0 \), almost surely. Now consider a limit point \( \bar{x} \) with the subsequence \( \{x^r_i\}_{j=1}^{\infty} \) converging to \( \bar{x} \). Using the definition of \( \bar{x}^r \), we have
\[
\lim_{j \rightarrow \infty} \bar{h}_i (\bar{x}_j^r, x^r_i) \leq \bar{h}_i (x_i, x_i), \quad \forall x_i \in X_i, \quad \forall i.
\]
(15)
Therefore, by letting \( j \rightarrow \infty \) and using the fact that \( \lim_{r \rightarrow \infty} \| \bar{x}^r - x^r \| = 0 \), almost surely, we obtain \( \bar{h}_i (\bar{x}_j, \bar{x}) \leq \bar{h}_i (x_i, \bar{x}) \), \( \forall x_i \in X_i, \forall i \), almost surely; which in turn, using the gradient consistency assumption, implies
\[
\langle \nabla f (\bar{x}) + d, x - \bar{x} \rangle \geq 0, \quad \forall x \in X, \quad \text{almost surely},
\]
for some \( d \in \partial g(\bar{x}) \), which completes the proof for the randomized block selection rule. Now consider the cyclic update rule with a limit point \( \bar{x} \). Due to the sufficient decrease bound (7), we have \( \lim_{r \rightarrow \infty} h(x^r) = h(\bar{x}) \). Furthermore, by taking the summation over (7), we obtain
\[
\sum_{r=1}^{\infty} \gamma^r \| \bar{x}^r - x^r \|^2 < \infty,
\]
and define a fixed block \( i \) and define \( \{r_k\}_{k=1}^{\infty} \) to be the subsequence of iterations that block \( i \) is updated. Clearly, \( \sum_{k=1}^{\infty} \gamma^r \| x_{i_k}^k - x_{i_k}^k \|^2 < \infty \) and \( \sum_{k=1}^{\infty} \gamma^r = \infty \), since \( \{\gamma^r\} \) is monotonically decreasing. Therefore, \( \liminf_{k \rightarrow \infty} \| \bar{x}_{i_k}^k - x_{i_k}^k \| = 0 \). Repeating the above argument with some slight modifications, which are omitted due to lack of space, we can show that \( \lim_{k \rightarrow \infty} \| \bar{x}_{i_k}^k - x_{i_k}^k \| = 0 \) implying that the limit point \( \bar{x} \) is a stationary point of (1).
4 Convergence Analysis: Iteration Complexity

In this section, we present iteration complexity analysis of the algorithm for both convex and non-convex cases.

4.1 Convex Case

When the function $f(\cdot)$ is convex, the overall objective function will become convex; and as a result of Theorem 1 if a limit point exists, it is a global minimizer of $f$. In this scenario, it is desirable to derive the iteration complexity bounds of the algorithm. Note that our algorithm employs linear combination of the two consecutive points at each iteration and hence it is different than the existing algorithms in \cite{2,4,20}. Therefore, not only in the cyclic case, but also in the randomized scenario, the iteration complexity analysis of PSCA is different than the existing results and should be investigated. Let us make the following assumptions for our iteration complexity analysis:

- The step-size is constant with $\gamma^r = \gamma < \frac{1}{L_0}$, $\forall r$.
- The level set $\{ x \mid h(x) \leq h(x^0) \}$ is compact and the next two assumptions hold in this set.
- The nonsmooth function $g(\cdot)$ is Lipschitz continuous, i.e., $|g(x) - g(y)| \leq L_g \| x - y \|$, $\forall x, y \in \mathcal{X}$. This assumption is satisfied in many practical problems such as (group) Lasso.
- The gradient of the approximation function $\tilde{f}_i(\cdot, y)$ is uniformly Lipschitz with constant $L_i$, i.e., $\| \nabla_{x_i} \tilde{f}_i(x_i, y) - \nabla_{x'_i} \tilde{f}_i(x'_i, y) \| \leq L_i \| x_i - x'_i \|$, $\forall x_i, x'_i \in \mathcal{X}_i$.

Lemma 2 (Sufficient Descent) There exists $\tilde{\beta}, \tilde{\beta} > 0$, such that for all $r \geq 1$, we have

- For randomized rule: $\mathbb{E}[h(x^{r+1}) \mid x^r] \leq h(x^r) - \tilde{\beta}\| \tilde{x}^r - x^r \|^2$.
- For cyclic rule: $h(x^{m(r+1)}) \leq h(x^{mr}) - \tilde{\beta}\| x^{m(r+1)} - x^{mr} \|^2$.

Proof The above result is an immediate consequence of (1) with $\tilde{\beta} \triangleq \beta \gamma \mu_{\min}$ and $\tilde{\beta} \triangleq \frac{\beta}{\gamma}$.

Due to the bounded level set assumption, there must exist constants $\bar{Q}, Q, R > 0$ such that

$$
\| \nabla f(x^r) \| \leq Q, \quad \| \nabla_{x_i} \bar{f}_i(\tilde{x}^r, x^r) \| \leq \bar{Q}, \quad \| x^r - x^* \| \leq R,
$$

for all $x^r$. Next we use the constants $Q, \bar{Q}$ and $R$ to bound the cost-to-go in the algorithm.

Lemma 3 (Cost-to-go Estimate) For all $r \geq 1$, we have

- For randomized rule: $\left( \mathbb{E}[h(x^{r+1}) \mid x^r] - h(x^*) \right)^2 \leq 2 \left( (Q + L_g)^2 + nL^2R^2 \right) \| \tilde{x}^r - x^r \|^2$
- For cyclic rule: $\left( h(x^{m(r+1)}) - h(x^*) \right)^2 \leq n-\frac{\theta^2}{(1-\gamma)^2}\| x^{m(r+1)} - x^{mr} \|^2$

for any optimal point $x^*$, where $L \triangleq \max_i \{ L_i \}$ and $\theta \triangleq \frac{L_g^2 + \bar{Q}^2 + 2nR^2\bar{L}^2(1-\gamma)^2}{2} + 2R^2L^2$.

Proof Here we only prove the randomized part result. The proof for the cyclic part is lengthy and omitted here due to space limitations. For randomized part, we first bound the conditional expected cost-to-go by

$$
\mathbb{E} \left[ h(x^{r+1}) - h(x^*) \mid x^r \right] \leq h(x^r) - h(x^*) = f(x^r) - f(x^*) + g(x^r) - g(x^*) \\
\leq \langle \nabla f(x^r), x^r - \tilde{x}^r \rangle + \langle \nabla f(x^r), \tilde{x}^r - x^r \rangle + L_g \| x^r - \tilde{x}^r \| + g(\tilde{x}^r) - g(x^*) \\
\leq (L_g + Q)\| \tilde{x}^r - x^r \| + \sum_{i=1}^n \langle \nabla_{x_i} f(x^r), \nabla_{x_i} f_i(\tilde{x}_i, x^r) - \nabla_{x_i} f_i(\tilde{x}_i, x^r) \rangle + g(\tilde{x}^r) - g(x^*) \\
\leq (L_g + Q)\| \tilde{x}^r - x^r \| + \sum_{i=1}^n \langle \nabla_{x_i} f(x^r) - \nabla_{x_i} f_i(\tilde{x}_i, x^r), \tilde{x}_i^r - x_i^r \rangle 
$$

(16)
where (i) is due to Lemma 2, the inequality (ii) is due to the convexity of $f(\cdot)$ and Lipschitz continuity of $g(\cdot)$; the third inequality is by (15). Furthermore, the last inequality is obtained by exploiting the first order optimality condition of the point $\tilde{x}_i$, i.e., $\langle \nabla_x f_i(\tilde{x}_i, x') - \nabla_x f_i(\tilde{x}_i, x'), \tilde{x}_i - x_i \rangle + g_i(\tilde{x}_i) - g_i(x_i) \leq 0$. In addition to the above inequality, on can easily deduce
\[
\left( \sum_{i=1}^{n} (\nabla_x f_i(x') - \nabla_x f_i(\tilde{x}_i, x'), \tilde{x}_i - x_i) \right)^2 = \left( \sum_{i=1}^{n} (\nabla_x f_i(x', x') - \nabla_x f_i(\tilde{x}_i, x'), \tilde{x}_i - x_i) \right)^2 \\
\leq n \sum_{i=1}^{n} L^2 ||x' - \tilde{x}_i||^2 \cdot ||\tilde{x}_i - x_i||^2 \leq nL^2 R^2 ||x' - \tilde{x}||^2.
\] (17)

Combining (16) and (17) will conclude the proof.

Lemma 2 and Lemma 3 yield to the iteration complexity bound in the following theorem. The proof steps of this result are similar to the ones in [24] and therefore omitted here for space reasons.

**Theorem 2** Define $\sigma \triangleq \frac{2\gamma \mu_{\min}}{2((l+L)n)^2 + nL^2 R^2}$ and $\tilde{\sigma} \triangleq \frac{\beta (1 - \gamma)^2}{nL^2 R^2}$. Then

- For randomized update rule: $\mathbb{E} [h(x^r)] - h(x^*) \leq \frac{\max \{ 4\sigma - 2, h(x^0) - h(x^*) \} \frac{1}{\rho} }{\sigma}$.
- For cyclic update rule: $h(x^{nm}) - h(x^*) \leq \frac{\max \{ 4\sigma - 2, h(x^0) - h(x^*) \} \frac{1}{\rho} }{\sigma}$.

**4.2 Non-convex Case**

In this subsection we study the iteration complexity of the proposed randomized algorithm for the general nonconvex function $f(\cdot)$ assuming constant step-size selection rule. This analysis is only for the randomized block selection rule. Since in the nonconvex scenario, the iterates may not converge to the global optimum point, the closeness to the optimal solution cannot be considered for the iteration complexity analysis. Instead, inspired by [27] where the size of the gradient of the objective function is used as a measure of optimality, we consider the size of the objective proximal gradient as a measure of optimality. More precisely, we define
\[
\nabla h(x) = x - \text{arg min}_{y \in \mathcal{X}} \left\{ \langle \nabla f(x), y - x \rangle + g(y) + \frac{1}{2} ||y - x||^2 \right\}.
\]
Clearly, $\nabla h(x) = 0$ when $x$ is a stationary point. Moreover, $\nabla h(\cdot)$ coincides with the gradient of the objective if $g \equiv 0$ and $\mathcal{X} = \mathbb{R}^n$. The following theorem, which studies the decrease rate of $||\nabla h(x)||$, could be viewed as an iteration complexity analysis of the randomized PSCA.

**Theorem 3** Consider randomized block selection rule. Define $T_c$ to be the first time that $\mathbb{E} [[\nabla h(x^r)]^2] \leq \epsilon$. Then $T_c \leq \frac{\kappa}{\epsilon}$ where $\kappa \triangleq \frac{2(L^2 + 2L + 2)h(x^0)^* - h(x^*)}{\beta}$ and $h^* = \min_{x \in \mathcal{X}} h(x)$.

**Proof** To simplify the presentation of the proof, let us define $\tilde{y}_i \triangleq \text{arg min}_{y_i \in \mathcal{X}} \langle \nabla_x f_i(x'), y_i - x_i \rangle + g_i(y_i) + \frac{1}{2} ||y_i - x_i||^2$. Clearly, $\nabla h(x^r) = (x^r_i - \tilde{y}_i)_{i=1}^n$. The first order optimality condition of the above optimization problem implies
\[
\langle \nabla_x f_i(x') + \tilde{y}_i - x_i, x_i - \tilde{y}_i \rangle + g_i(x_i) - g_i(\tilde{y}_i) \geq 0, \quad \forall x_i \in \mathcal{X}.
\] (18)

Furthermore, based on the definition of $\tilde{x}_i$, we have
\[
\langle \nabla_x f_i(\tilde{x}_i, x'), x_i - \tilde{x}_i \rangle + g_i(x_i) - g_i(\tilde{x}_i) \geq 0, \quad \forall x_i \in \mathcal{X}.
\] (19)

Plugging in the points $\tilde{x}_i$ and $\tilde{y}_i$ in (18) and (19); and summing up the two equations will yield to
\[
\langle \nabla_x f_i(\tilde{x}_i, x') - \nabla_x f_i(\tilde{x}_i, x'), x_i - \tilde{x}_i \rangle + x_i - \tilde{x}_i + \tilde{y}_i - \tilde{x}_i \rangle \geq 0.
\]

Using the gradient consistency assumption, we can write
\[
\langle \nabla_x f_i(\tilde{x}_i, x') - \nabla_x f_i(\tilde{x}_i, x'), x_i - \tilde{x}_i \rangle + x_i - \tilde{x}_i + \tilde{y}_i - \tilde{x}_i \rangle \geq 0.
\]
or equivalently, \(\langle \nabla x_i f_i(x_i^r, x^r) - \nabla x_i f_i(x_i^r, x^r) + x_i^r - \hat{x}_i^r, \hat{y}_i^r - \hat{x}_i^r \rangle \geq \|\hat{x}_i^r - \hat{y}_i^r\|^2\). Applying Cauchy-Schwarz and the triangle inequality will yield to

\[
\left(\|\nabla x_i f_i(x_i^r, x^r) - \nabla x_i f_i(x_i^r, x^r)\| + \|x_i^r - \hat{x}_i^r\|\right)\|\hat{y}_i^r - \hat{x}_i^r\| \geq \|\hat{x}_i^r - \hat{y}_i^r\|^2.
\]

Since the function \(f_i(\cdot, x)\) is Lipschitz, we must have

\[
\|\hat{x}_i^r - \hat{y}_i^r\| \leq (1 + L_i)\|x_i^r - \hat{x}_i^r\|
\]

(20)

Using the inequality (20), the norm of the proximal gradient of the objective can be bounded by

\[
\|\tilde{h}(x^r)\|^2 = \sum_{i=1}^n \|x_i^r - \tilde{y}_i^r\|^2 \leq 2 \sum_{i=1}^n (\|x_i^r - \hat{x}_i^r\|^2 + \|\hat{x}_i^r - \tilde{y}_i^r\|^2)
\]

\[
\leq 2 \sum_{i=1}^n (\|x_i^r - \hat{x}_i^r\|^2 + (1 + L_i)^2\|x_i^r - \hat{x}_i^r\|^2) \leq 2(2L + L^2)\|x^r - \hat{x}^r\|^2.
\]

Combining the above inequality with the sufficient decrease bound in (8), one can write

\[
\sum_{r=0}^T \mathbb{E} \left[\|\tilde{h}(x^r)\|^2\right] \leq \sum_{r=0}^T \frac{2(2 + 2L + L^2)}{\beta} \mathbb{E} \left[\|x^r - \hat{x}^r\|^2\right] \leq \sum_{r=0}^T \frac{2(2 + 2L + L^2)}{\beta} \mathbb{E} \left[h(x^r) - h(x^{r+1})\right]
\]

\[
\leq \frac{2(2 + 2L + L^2)}{\beta} \mathbb{E} \left[h(x^0) - h(x^{T+1})\right] \leq \frac{2(2 + 2L + L^2)}{\beta} \mathbb{E} \left[h(x^0) - h^*\right] = \kappa,
\]

which implies that \(T_\varepsilon \leq \frac{\kappa}{\beta}\).

5 Numerical Experiments:

In this short section, we compare the numerical performance of the proposed algorithm with the classical serial BCD methods. The algorithms are evaluated over the following Lasso problem:

\[
\min x \frac{1}{2}\|Ax - b\|_2^2 + \lambda\|x\|_1,
\]

where the matrix \(A\) is generated according to the Nesterov’s approach [5]. Two problem instances are considered: \(A \in \mathbb{R}^{2000 \times 10,000}\) with 1% sparsity level in \(x^\ast\) and \(A \in \mathbb{R}^{1000 \times 100,000}\) with 0.1% sparsity level in \(x^\ast\). The algorithm parameters and the approximation functions are chosen exactly the same as the numerical experiments in [9], except our block selection rule is different. Figure 1 and Figure 2 illustrate the behavior of cyclic and randomized parallel BCD method as compared with their serial counterparts. The variable \(q\) shows the number of processors and on each processor we update 40 scalar variables in parallel. As can be seen in Figure 1 and Figure 2, parallelization of the BCD algorithm results in more efficient algorithm. However, the computational gain does not grow linearly with the number of processors. In fact, we can see that after some point, the increase in the number of processors lead to slower convergence. This fact is due to the communication overhead among the processing nodes which dominates the computation time.

Figure 1: Lasso Problem: \(A \in \mathbb{R}^{2,000 \times 10,000}\)

Figure 2: Lasso Problem: \(A \in \mathbb{R}^{1,000 \times 100,000}\)
