Since January 2020 Elsevier has created a COVID-19 resource centre with free information in English and Mandarin on the novel coronavirus COVID-19. The COVID-19 resource centre is hosted on Elsevier Connect, the company's public news and information website.

Elsevier hereby grants permission to make all its COVID-19-related research that is available on the COVID-19 resource centre - including this research content - immediately available in PubMed Central and other publicly funded repositories, such as the WHO COVID database with rights for unrestricted research re-use and analyses in any form or by any means with acknowledgement of the original source. These permissions are granted for free by Elsevier for as long as the COVID-19 resource centre remains active.
Factors associated with post-traumatic growth in response to the COVID-19 pandemic: Results from a national sample of U.S. military veterans

\textbf{ABSTRACT}

\textbf{Rationale:} The COVID-19 pandemic has had numerous negative effects globally, contributing to mortality, social restriction, and psychological distress. To date, however, the majority of research on the psychological impact of the COVID-19 pandemic has focused on negative psychological outcomes, such as depression, anxiety, and posttraumatic stress disorder (PTSD).

\textbf{Objective:} Although there is debate about the constructive vs. illusory nature of post-traumatic growth (PTG), it has been found to be prevalent in a broad range of trauma survivors, including individuals affected by the COVID-19 pandemic. The objective of this study was to identify pre- and peri-pandemic factors associated with pandemic-related PTG in U.S. veterans.

\textbf{Methods:} Data were analyzed from the National Health and Resilience in Veterans Study, which surveyed a nationally representative cohort of 3078 U.S. veterans. A broad range of pre-pandemic and 1-year peri-pandemic factors associated with pandemic-related PTG were evaluated. Curve estimation and receiver operating characteristic curve analyses were conducted to characterize the association between pandemic-related PTSD symptoms and PTG.

\textbf{Results:} Worries about the effect of the pandemic on one’s physical and mental health, PTG in response to previous traumas (i.e., new possibilities and improved interpersonal relationships), and pandemic-related avoidance symptoms were the strongest correlates of pandemic-related PTG. An inverted-U shaped relationship provided the best fit to the association between pandemic-related PTSD symptoms and endorsement of PTG, with moderate severity of PTSD symptoms optimally efficient in identifying veterans who endorsed PTG.

\textbf{Conclusions:} Results of this study suggest that psychosocial interventions that promote more deliberate and organized rumination about the pandemic and enhance PTG in response to prior traumatic events may help facilitate positive psychological changes related to the COVID-19 pandemic in U.S. military veterans. Longitudinal studies on functional correlates of PTG may help inform whether these changes are constructive vs. illusory in nature.

1. Introduction

The COVID-19 pandemic has had a pervasive global impact, causing mortality, social restriction, and psychological distress (Reger et al., 2020). Consequently, there have been concerns of a possible surge in mental health problems in the general public, as well as high-risk populations, such as individuals with pre-existing psychiatric conditions (Reger et al., 2020). However, despite these grim forecasts, extant studies have observed stability in prevalence of severe psychological distress during the pandemic relative to the previous year (Breslau et al., 2021; Hill et al., 2021). Further, deaths by suicide have actually declined in the U.S. (Ahmad and Anderson, 2021) as well as in 21 upper-middle

and high-income countries in 2020 (Pirkis et al., 2021). Other outcomes, such as the prevalence of suicidal ideation or alcohol use disorder have also been found to be relatively stable among U.S. military veterans nine-months into the pandemic (Na et al., 2021a,b; Richter et al., 2021; Pietrzak et al., 2021).

To date, the majority of research on the mental health impact of the COVID-19 pandemic has focused on negative outcomes such as depression, anxiety, posttraumatic stress disorder (PTSD), and suicidality (Czeisler et al., 2020; Ettman et al., 2020; Krishnamoorthy et al., 2020; Na et al., 2021a,b). In contrast, relatively few studies have focused on potentially salutogenic outcomes such as posttraumatic growth (PTG) (Asmundson et al., 2021; Hamam et al., 2021; Pietrzak et al., 2021; Tamiolaki and Kalaitzaki, 2020; Vazquez et al., 2021; Zhai et al., 2021). PTG is defined as positive, meaningful psychological changes that individuals may experience after struggling with traumatic and stressful life events (Zoellner and Maercker, 2006), and has been linked to improved functioning (Tsai et al., 2015), as well as greater resilience to subsequent traumatic events (Tsai et al., 2016). Previous studies have also found that PTG could result from various traumas, including combat exposure (Pietrzak et al., 2010), assault (Kleim and Ehlers, 2009), and imprisonment during war (Feder et al., 2008). PTG is a complex phenomenon, with ongoing debate regarding its conceptualization and adaptivity (Zoellner and Maercker, 2006; Asmundson et al., 2021).

Specifically, it has been suggested that while PTG may be real/constructive and lead to positive psychological changes, it is also possible that it may partly reflect dysfunctional attempts to cope with stressful events, such as avoidant or defensive coping strategies that lead to increased distress (Boermer et al., 2017). For example, a recent study of Canadian and U.S. adults with high levels of COVID-related distress found that among those with high levels of PTG, 65% had a profile consistent with real/constructive growth (i.e., low COVID-19 stress-related disability and stable levels of distress over time), while 35% had a profile consistent with illusory growth (i.e., high COVID-19 stress-related disability and worsening distress over time) (Asmundson et al., 2021).

Military veterans are a unique population with various exposures to potentially traumatic and stressful life events, such as military training, deployment, and combat (Marini et al., 2020). However, it is unclear whether this unique history, as well as both adverse and positive mental health experiences related to it, may help mitigate the deleterious effects of such events (i.e., stress inoculation) or render this population more vulnerable to future disasters (i.e., stress sensitization), such as the COVID-19 pandemic.

An emerging body of research conducted before the COVID-19 pandemic has identified demographic, psychosocial, and personality factors associated with PTG, which have guided the selection of variables examined in the present study. Concerning demographics, older age (Patrick and Henrie, 2016; Vishnevsky et al., 2010), female gender (Vishnevsky et al., 2010), non-Caucasian ethnicity (Gallaway et al., 2011; Kleim and Ehlers, 2009; Mitchell et al., 2013; Vishnevsky et al., 2010), and previous life stressors such as traumatic exposures (Hafstad et al., 2011; Laufer and Solomon, 2006) have been positively linked to PTG. Although somewhat mixed, in general, psychiatric conditions such as PTSD (Morgan et al., 2017; Pietrzak et al., 2010; Tsai et al., 2015), depression (Helgeson et al., 2006; Morrill et al., 2008; Powell et al., 2003; Xu et al., 2016), and anxiety (Xu et al., 2016) have been negatively associated with PTG. However, it should be also noted that the association between PTSD and PTG is best characterized as a curvilinear, inverted U-shaped relationship, with moderate levels of distress associated with greater PTG relative to low or severe levels of distress (Kleim and Ehlers, 2009). Personality factors such as extraversion (Linley and Joseph, 2004; Tedeschi and Calhoun, 2004), agreeableness (Linley and Joseph, 2004), conscientiousness (Linley and Joseph, 2004), and openness to experiences (Linley and Joseph, 2004; Tedeschi and Calhoun, 2004) as well as protective psychosocial factors such as optimism (Bostock et al., 2009; Helgeson et al., 2006; Linley and Joseph, 2004; Prati and Pietrantoni, 2009; Tedeschi and Calhoun, 2004), social support (Forstmeier et al., 2009; Prati and Pietrantoni, 2009) and/or connectedness (McMillen et al., 1997; Tsai et al., 2015), religiosity/spirituality (Kleim and Ehlers, 2009; Prati and Pietrantoni, 2009; Tsai et al., 2015), and purpose in life (Tsai et al., 2015), have also been positively associated with PTG.

Studies that examined PTG during the COVID-19 pandemic have shown factors such as female gender (Kalsiiztaki, 2021; Pietro-Ursua and Jodar, 2020; Yildiz, 2021), being married (Li et al., 2021b), greater adverse childhood experiences (Chi et al., 2020), higher economic status (Yildiz, 2021), greater psychological distress (Chi et al., 2020; Koliouli and Canellopoulos, 2021), knowing someone who died of COVID-19 complications (Pietro-Ursua and Jodar, 2020), actual COVID-19 infection (Pietro-Ursua and Jodar, 2020), and COVID-related PTSD symptoms (Pietrzak et al., 2021) to be linked to pandemic-related PTG.

In a recent study of a population-based sample of 3078 U.S. veterans, we found that 43.3% reported moderate or greater levels of COVID-19 pandemic-related PTG nine months into the pandemic; veterans who screened positive for pandemic-related PTSD symptoms reported a substantially higher prevalence of PTG than those who did not screen positive for these symptoms (Pietrzak et al., 2021). Further, greater pandemic-related improvements in interpersonal relationships and appreciation of life were associated with a lower likelihood of suicidal thoughts during the pandemic. However, this study did not examine pre- and peri-pandemic factors associated with PTG during the COVID-19 pandemic. Characterization of such factors may help inform clinical and policy interventions that may help veterans and other high-risk populations develop PTG and potentially be more resilient in future disasters. Toward this end, we analyzed data from the National Health and Resilience in Veterans Study (NHRVS) to examine a broad constellation of pre- and peri-pandemic risk and protective factors, informed by prior literature (Tsai et al., 2015, 2016), associated with pandemic-related PTG. Additionally, changes in household income (Pothisiri and Vicerra, 2021), trauma exposures (Lahav, 2020), and protective psychosocial characteristics (Li et al., 2021a; Yu et al., 2020) were also examined in light of data suggesting that such changes were associated with psychological distress during the COVID-19 pandemic.

2. Methods

2.1. Participants

Data were analyzed from the 2019–2020 NHRVS, which surveyed a nationally representative sample of U.S. military veterans. A total of 4069 veterans completed the Wave 1 (median completion date: 11/21/2019) survey before the first documented COVID-19 case in the U.S. and 3078 (75.6%) completed a 1-year follow-up Wave 2 (median completion date: 11/14/2020) survey. Hereafter, the Wave 1 survey will be referred to as “pre-pandemic survey” and Wave 2 survey will be referred to as “peri-pandemic survey.” As described in greater detail elsewhere (Tsai et al., 2021), the NHRVS sample was drawn from KnowledgePanel®, a survey research panel of more than 50,000 U.S. households maintained by Ipsos, a survey research firm. To ensure generalizability of the results to the U.S. veteran population, poststratification weights were computed based on the demographic distribution of veterans in the U.S. Census Current Population Survey.

2.2. Assessments

Post-traumatic growth. COVID-19–associated PTG was assessed using the Posttraumatic Growth Inventory-Short Form (Cann et al., 2010; PTGI-SF) at Wave 2 (α = 0.92). Total scores (range: 0-50) and five subscales including personal strength, relating to others, new possibilities, spiritual change, and appreciation of life were assessed. Sample item: “Please indicate the degree to which you experienced these changes in your life as a result of the COVID-19 pandemic: I have a
greater sense of closeness with others.” Endorsement of “moderate,” “great,” or “very great” growth on any of the PTGI-SF items was indicative of PTG. Given that the distribution of PTGI-SF scores was zero-inflated, non-normal, and positively skewed (Kolmogorov-Smirnov test statistic = 0.19, p < 0.001), we dichotomized responses based on moderate or greater endorsement of any item; this approach to operationalizing endorsement of PTG has been used in a meta-analysis on the prevalence of PTG (Wu et al., 2019), as well as our recent study on the prevalence of COVID-19 pandemic-related PTG in the current sample (Pietrzak et al., 2021).

Background characteristics. Table 1 presents a detailed description of measures used to assess sociodemographic characteristics, psychological distress, cumulative trauma burden, adverse childhood experiences, physical health conditions, history of mental health treatment, personality traits (i.e., emotional stability, extraversion, openness to experience, agreeableness, and conscientiousness), social connectedness (i.e., emotional/instrumental social support, secure attachment style, and structural social support), and protective psychosocial factors (i.e., resilience, purpose in life, gratitude, community integration, optimism, social support, and curiosity/exploration).

Pandemic-associated factors. Table 1 presents a detailed description of measures used to assess COVID-19 infection status of veterans, household members, and non-household members; hours spent consuming COVID-related media; and knowing someone who died of COVID-19 using a questionnaire developed by the National Center for PTSD. Questions from the Coronavirus Health Impact Survey (National Institute of Mental Health Intramural Research Program Mood Spectrum Collaboration & Child Mind Institute of the NYS Nathan S. Kline Institute for Psychiatric Research, 2020) were used to assess COVID-related worries, social restriction stress, and financial difficulties.

2.3. Data analysis

Item-level missing data (<5%), which were missing completely at random (MCAR) as per Little’s MCAR test (all ps > 0.50), were imputed using chained equations. Data analyses proceeded in five steps. First, we computed bivariate correlations between any pandemic-related PTG and a broad range of background characteristics and pandemic-related variables (see Table 1). Second, variables that were significantly associated with pandemic-related PTG at the p < 0.05 level in bivariate analyses were entered into a hierarchical binary logistic regression analysis; background characteristics were entered in step 1, pandemic-related variables in step 2, and change variables in step 3. Third, we conducted planned post-hoc analyses of multi-dimensional variables (e.g., PTSD symptoms, protective psychosocial characteristics, COVID-19 pandemic-related stressors) to identify aspects of these variables that were most strongly associated with PTG; alpha was set to 0.01 for these analyses to reduce likelihood of Type I error. Fourth, significant variables from the logistic regression analysis were entered into a relative importance analysis, which computed the explained variance in pandemic-related PTG that is attributable to each independent variable while accounting for intercorrelations among these variables (Toni-dandel and LeBreton, 2010). This analysis yields a relative weight (% variance explained) for each independent variable that collectively sums to the total R² in predicting a dependent variable (weights are re-scaled to sum to 100% of the explained variance); this analytic approach represents an extension of regression modeling that allows one to model intercorrelations among independent variables when determining the relative importance of each independent variable in predicting variance in a dependent variable. Fifth, to examine the nature of the association between severity of PTSD symptoms and PTG, we fitted linear and quadratic functions between the severity of pandemic-related PTSD symptoms and probability of endorsing PTG from the logistic regression model. An analysis of variance was used to determine which function provided the best fit to these data and explained the most variance in predicting probability of endorsing PTG. We then conducted a receiver

| Table 1 Pre- and peri-pandemic factors examined in relation to pandemic-related post-traumatic growth in U.S. veterans. |
|---------------------------------|--------------------------------------------------------------------------------------------------|
| Sociodemographic characteristics | Age, gender, race (white vs non-white), education (college graduate or higher vs up to high school diploma), marital status (married/ living with partner vs unmarried), income ($60,000 or more vs less than $60,000), employment (working vs retired), and combat status (no combat exposure vs combat) |
| Background characteristics | Psychological distress MDD symptoms – participant responses on the two depressive symptoms of the PHQ-4 occurring in the past two weeks (≥ 3); a score ≥ 3 was indicative of a positive screen for MDD (Kroenke et al., 2009); PTSD symptoms- assessed with the PTSD Checklist for DSM-5; a score ≥ 33 was indicative of a positive screen for PTSD (Weathers et al., 2013b); GAD symptoms – participant responses on the two generalized anxiety items of the PHQ-4 occurring in the past two weeks (a score ≥ 3 was indicative of a positive screen for GAD (Kroenke et al., 2009). |
| Cumulative trauma burden | Count of potentially traumatic events on the Life Events Checklist for DSM-5 (LEG-5;Weathers et al., 2013b). |
| Adverse childhood experiences | Score on Adverse Childhood Experiences Questionnaire (Felitti et al., 1998). |
| Number of medical conditions | Sum of number of medical conditions endorsed in response to question: “Has a doctor or healthcare professional ever told you that you have any of the following medical conditions?” (e.g., arthritis, cancer, diabetes, heart disease, asthma, kidney disease). Range: 0–24 conditions. |
| Personality traits | Assessed using the Ten-Item Personality Inventory (TIPI; Gosling et al., 2003), a 10-item self-report brief measure of the “Big Five” personality traits of emotional stability (anxious vs confident and calm), extraversion (outgoing vs reserved), openness to experience (imaginative and inventive vs cautious and routine-like), agreeableness (friendly and cooperative vs detached), and conscientiousness (efficient and organized vs careless). |
| Engagement in mental health treatment | Positive endorsement of current treatment with a psychiatric or emotional problem? “Are you currently taking prescription medication for a psychiatric or emotional problem?” “Are you currently receiving psychotherapy or counseling for a psychiatric or emotional problem?” |
| Religiosity/spirituality | Score on the Duke University Religion Index (DUREL; Koenig and Bussing, 2010). |
| Social connectedness | Number of close friends and family members. Choose one: a) I am somewhat uncomfortable being close to others; b) I find it relatively easy to get close to others (secure); c) I find that others are reluctant to get as close as I would like (Hazan and Shaver, 1990). |
| Structural social support | Medical Outcomes Study Social Support Scale-5; 5 items assessing how often each type of support is available when needed (e.g., “Someone to confide in or talk to about your problems”) on a 5-point Likert scale: 1 – none of the time to 5 – all of the time. Higher scores reflect greater perceived social support (Sherbourne and Stewart, 1991). |
| Secure attachment | Connor-Davidson Resilience Scale-10 (CDRISC-10); 10 items (e.g., “I am able to adapt when changes occur”) on a 5-point Likert scale (1 = not at all true to 5 = true nearly all the time; Campbell-Sills and Steen, 2007). |

(continued on next page)
operating characteristic (ROC) curve analysis to identify the optimally efficient threshold of pandemic-related PTSD symptoms associated with endorsement of PTG.

### 3. Results

Table 2 shows sample characteristics, and results of bivariate correlations and a regression model examining factors associated with COVID-19 pandemic-related PTG.

Results of a multivariable logistic regression model revealed that background characteristics associated with pandemic-related PTG included female gender, non-White race/ethnicity, agreeableness, protective psychosocial characteristics (post-hoc analysis: purpose in life, OR = 1.04, 95% CI = 1.01–1.07), religiosity/spirituality, and PTG in relation to earlier trauma (post-hoc analysis: relating to others: OR = 1.10, 95% CI = 1.05–1.14; new possibilities: OR = 1.09, 95% CI = 1.05–1.13). Pandemic-related factors associated with PTG included pandemic-related worries (post-hoc analysis: physical health: OR = 1.22, 95% CI = 1.07–1.38; mental/emotional health: OR = 1.16, 95% CI = 1.04–1.30), social restriction stress, (post-hoc analysis: stress of changes in family contacts: OR = 1.30, 95% CI = 1.14–1.48; stress of changes in social contacts: OR = 1.23, 95% CI = 1.08–1.39); financial difficulties (post-hoc analysis: stability of living situation: OR = 1.30, 95% CI = 1.15–1.46), and PTSD symptoms, (i.e., avoidance: OR = 1.24, 95% CI = 1.13–1.36).

Fig. 1 shows results of a relative importance analysis of factors associated with pandemic-related PTG. Greater worries about the effect of the pandemic on one’s physical (15.3% relative variance explained (RVE)) and mental health (14.2% RVE); greater PTG in the form of new possibilities (13.3% RVE) and improved relationships with others (12.4%) related to pre-pandemic traumatic events; greater avoidance symptoms related to the pandemic (10.6% RVE); and greater stress of changes in family (9.2% RVE) and social (8.8% RVE) contacts explained the majority (>80%) of variance in pandemic-related PTG.

Results of a curve estimation analysis of the relation between severity of pandemic-related PTSD symptoms and probability of endorsing PTG revealed that a quadratic, inverted-U shaped function provided a better fit to the data than a linear function ($p = −0.32, t = 8.82, p < 0.001; R^2_{	ext{quadratic}} = 0.33$ vs. $R^2_{\text{linear}} = 0.31$). Further, results of ROC curve analyses indicated that a score of 3 on the 4-item PCL-5, which is lower than the cut score of 5 used to identify positive screen for PTSD (sensitivity = 0.41, specificity = 0.82; positive likelihood ratio: 2.32, 95% CI = 2.05–2.61) and that a score of 2 (i.e., moderate severity) of avoidance symptoms (sensitivity = 0.29, specificity = 0.88; positive likelihood ratio: 2.35, 95% CI = 2.02–2.73) were optimally efficient in differentiating veterans who endorsed PTG.

### 4. Discussion

To our knowledge, this study is the first to examine factors associated with PTG during the COVID-19 pandemic in a nationally representative sample of U.S. military veterans. Results highlight that among a broad range of clinical and psychosocial factors, worries about the effect of the pandemic on one’s physical and mental health, PTG in response to pre-pandemic traumatic life events, and greater severity of pandemic-related avoidance symptoms were the strongest correlates of pandemic-related PTG. Further, pandemic-related social restriction stress, most notably stress of changes in family and social contacts, were additionally strongly linked to PTG.

Worries about the effect of the pandemic on one’s physical and mental health explained the most variance in pandemic-related PTG. This finding parallels a recent online survey of 805 US young adults, which similarly found that greater COVID-19-related worries were positively associated with PTG during the pandemic (Hyun et al., 2021). However, another cross-sectional survey in Portugal and the UK conducted during the pandemic found no differences in anxiety symptoms

between those who did and did not report PTG (Stallard et al., 2021). Nevertheless, our finding is consistent with prior studies suggesting that psychological distress may help spur the process of PTG (Kleim and Ehlers, 2009; Sattler et al., 2014; Sigveland et al., 2012), with greater levels of PTG occurring among individuals with at least moderate levels of distress. In support of this notion, our prior study of this cohort revealed markedly higher prevalence of PTG among veterans who screened positive for pandemic-related PTSD symptoms (Pietrzak et al., 2021). Further, post-hoc analyses revealed that reporting being “very” or “extremely” worried about the effect of the pandemic on one’s physical and mental health were associated with the highest probability of reporting pandemic-related PTG (>55% and >65%, respectively). This finding may, at least in part, be explained by PTG reflecting dysfunctional attempts to cope with stressful events (Boerner et al., 2017). Indeed, a recent study found that among individuals who experienced high levels of PTG during the COVID-19 pandemic, approximately one-third reported higher COVID-19-related functional impairment and worsening distress (Asmundson et al., 2021). Another interpretation of this finding is that greater worries related to how the pandemic might affect one’s health may have led to more deliberate, organized, and controlled rumination about the pandemic. Indeed, prior work has suggested that deliberate rumination, often in conjunction with a strong social support system, can help foster PTG (Tedeschi and Calhoun, 2004).

Another noteworthy finding of this study is that veterans who reported greater PTG in relation to prior, pre-pandemic traumatic life events were more likely to show PTG in response to the COVID-19 pandemic. To our knowledge, the current study is the first to find that PTG in response to earlier life traumas—specifically perceiving new possibilities for one’s life and improved interpersonal relationships—may help foster PTG to a subsequent trauma. It also extends our previous finding showing that greater PTG—specifically perceptions of personal strength in response to earlier life traumas—may help promote resilience to subsequent traumatic events (Tsai et al., 2016). Veterans who endorsed PTG in relation to pre-pandemic traumas may have a personality style characterized by a greater ability to persevere, solicit support, and grow in response to stressful life events, and may be more likely to employ adaptive coping strategies that may help promote PTG and overall adaptation to the COVID-19 pandemic (Connor and Flachsbart, 2007; Haas, 2015; Seery et al., 2010). Greater wisdom has also been found to buffer the deleterious effect of adverse life events on well-being in older adults (Ardelt and Jeste, 2018).

Avoidance symptoms of PTSD related to the pandemic also explained a considerable proportion of variance in pandemic-related PTG. This finding parallels previous research suggesting that greater severity of avoidance symptoms may contribute to and maintain PTG over time in veterans (Whealin et al., 2020), as well as civilians (Hall et al., 2015; Lowe et al., 2013). It is important to note that avoidance symptoms are one of the core symptoms of PTSD (i.e., avoidance of distressing
trauma-related information, thoughts, and feelings, as well as external reminders), and strongly associated with high stress and worse prognosis (Perkonigg et al., 2005). Thus, this finding is consistent with prior research suggesting that the relationship between distress and PTG as a curvilinear and inverted U-shaped, with moderate levels of PTSD symptoms associated with higher levels of PTG (Kleim and Ehlers, 2009; Tsai et al., 2015; Whealin et al., 2020). Indeed, in the current study, a quadratic, inverted U-shaped association was found to best characterize the association between pandemic-related PTSD symptoms and probability of endorsing PTG. Further, a score of 3 on the 4-item PCL-5 and 2 on the avoidance item, which are indicative of moderate severity of PTSD symptoms, were optimally efficient in identifying veterans who endorsed PTG. Of note, this association may also partly reflect engagement in dysfunctional coping strategies such as avoidant coping skills (Boerner et al., 2017) or illusory aspects of PTG (Asmundson et al., 2021). Further longitudinal studies that examine functional correlates of PTG would be helpful in determining the potential constructive/adaptive utility of PTG.

Social restriction stress related to changes in family contacts and social contacts also explained a considerable proportion of variance in pandemic-related PTG. Veterans who have experienced heightened stress due to social restrictions may have gained more appreciation of interpersonal relationships, one of the core domains of PTG, which may have in turn contributed to their being more likely to report pandemic-related PTG. It is possible that veterans with greater social stressors during the pandemic may have been more likely to engage with loved ones using alternative modalities of connecting (e.g., virtual platforms, telephone, texting), which may have helped them process their thoughts and experiences related to the pandemic in a supportive context. Many of the other correlates of pandemic-related PTG identified in the current study (e.g., religiosity/spirituality), each of which explained substantially less variance than the factors noted above, are similar to those identified in prior studies of PTG (Gallaway et al., 2011; Kalaitzaki, 2021; Kleim and Ehlers, 2009; Vishnevsky et al., 2010).

4.1. Limitations

This study has several limitations. First, while nationally representative, the sample was comprised predominantly of older, male, and White veterans, which makes it difficult to generalize results to more diverse samples of veterans, as well as non-veteran populations. Second, we employed self-report screening instruments to assess all measures. Further research using structured clinical interviews is needed to replicate the results reported herein. Third, although this was a prospective cohort study, given the cross-sectional nature of the surveys and limited follow-up time frame, it is difficult to draw conclusions regarding temporal/causal associations between identified correlates of PTG, whether PTG will be maintained over time, or whether PTG reflects real/constructive or illusory growth. Longitudinal studies are needed to examine these questions. Fourth, the PTGI-SF, which was used to assess pandemic-related PTG in the current study, does not allow one to assess PTG depreciation or negative changes that may happen after a trauma (Cann et al., 2010; Taku et al., 2021). Lastly, PTG was assessed dichotomously due to the zero-inflated, non-normal, and positively skewed distribution of PTGI-SF scores. Further research is needed to evaluate the full range of both positive and negative psychological changes related to the COVID-19 pandemic using an assessment scale that captures the entire spectrum of PTG.

5. Conclusion

This is the first known study to examine factors associated with pandemic-related PTG in a population-based sample of U.S. military veterans. Results suggest that health-related worries, PTG in response to pre-pandemic traumas, and avoidance symptoms explained the majority of the variance in pandemic-related PTG. The results underscore the importance of assessing both adverse and salutogenic psychological effects of the pandemic, and of evaluating the potential efficacy of psychosocial interventions to help promote PTG (Roepke, 2015). Further research is needed to replicate and extend these results to other high-risk populations; identify mechanisms leading to increased PTG during the pandemic; and evaluate the efficacy of interventions to help promote PTG.
