ABSTRACT

Context. The Λ cold dark matter (ΛCDM) scenario is able to describe the Universe at large scales, but clearly shows some serious difficulties at small scales. The core-cusp question is one of these difficulties: the inner dark matter (DM) density profiles of spiral galaxies generally appear to be cored, without the $r^{-1}$ profile that is predicted by N-body simulations in the above scenario.

Aims. It is well known that in a more physical context, the baryons in the galaxy might backreact and erase the original cusp through supernova explosions. Before the efficiency and the presence of this effect is investigated, it is important to determine how wide and frequent the discrepancy between observed and N-body-predicted profiles is and what its features are.

Methods. We used more than 3200 quite extended rotation curves (RCs) of good quality and high resolution of disk systems that included normal and dwarf spirals as well as low surface brightness galaxies. The curves cover all magnitude ranges. All these RCs were condensed into 26 coadded RCs, each of them built with individual RCs of galaxies of similar luminosity and morphology. We performed mass models of these 26 RCs using the Navarro-Frenk-White (NFW) profile for the contribution of the DM halo to the circular velocity and the exponential Freeman disk for the contribution of the stellar disk.

Results. The fits are generally poor in all the 26 cases: in several cases, we find $\chi^2_{red} > 2$. Moreover, the best-fitting values of three parameters of the model ($c$, $M_{200}^*\equiv\sigma^2\,R_200^*$, and $M_{hi}$) combined with those of their 1σ uncertainty clearly contradict well-known expectations of the ΛCDM scenario. We also tested the scaling relations that exist in spirals with the outcome of the current mass modeling: the modeling does not account for these scaling relations.

Conclusions. The results of testing the NFW profile in disk systems indicate that this DM halo density law cannot account for the kinematics of the whole family of disk galaxies. It is therefore mandatory for the success of the ΛCDM scenario in any disk galaxy of any luminosity or maximum rotational velocity to transform initial cusps into the observed cores.

Key words. galaxies: kinematics and dynamics – dark matter

1. Introduction

Dark matter (DM), which makes up 85% of all the matter in the Universe, is still one of the most elusive mysteries in present-day physics. The existence of nonbaryonic DM is considered a fact that has been proved by Planck measurements of the cosmic microwave background (CMB), for instance. This component is thought to be made of nonrelativistic particles that can be described by a collisionless fluid that interacts with ordinary particles (baryons) through gravity alone because the cross section for nucleons is thought to be only $\sim 10^{-26}$ cm$^2$ (e.g., Jungman et al. 1996).

At present, Λ cold dark matter (ΛCDM) is known as a very successful cosmological scenario in describing the formation and evolution of the large-scale structures of the Universe (Frenk et al. 1985; Bode et al. 2001). The N-body simulations in this scenario have been able to resolve the current structure of virialized objects from clusters to dwarf galaxies. The simulations have shown that the ΛCDM power spectrum of the density perturbations combined with the collisionless nature of the CDM particles lead in any virialized object from clusters to dwarf galaxies to a very peculiar cuspy dark halo density profile: $\rho_{DM} \propto r^{-1}$. In detail, dark halos around galaxies are well described by the Navarro-Frenk-White (NFW) profile (Navarro et al. 1996, 1997).

It is also known that this sharp central cusp of the DM density distribution strongly contradicts the analysis of the kinematics of disk galaxies. For the first time, Gentile et al. (2004) showed in mass models obtained from six high-quality extended RCs that combined optical and 2D HI data overwhelming evidence for cored dark halo distributions beyond any statistical or bias uncertainty. More references on this topic is given in Salucci (2019).

About 100 RCs of the above quality have been thoroughly investigated so far, and the results have led to a similar decisive support in favor of the DM halo cored distribution (e.g., Adams et al. 2012; Donato et al. 2009; Weinberg et al. 2015; Simon et al. 2005; de Blok & Bosma 2002; Spekkens et al. 2005). The current status of the analysis of individual RCs is described in Korsaga et al. (2018, 2019a), who obtained mass models of 31 spiral and irregular galaxies, derived using hybrid rotation curves that combined high-resolution optical GHASP Fabry-Perot Hα RCs with extended radio WHISP HI RCs.
Moreover, for each galaxy, the analysis took advantage of high-quality 3.4 μm WISE photometry, which is a fair indicator of the stellar disk mass. Korsaga and collaborators found that independent measurements (e.g., Reyes et al. 2012; Mandelbaum et al. 2016) or methods alternative to the RC analysis and then compared with 2019). Moreover, newly proposed scenarios for the DM particles may be changed properly. The processes within a collisionless dark particle scenario to have been proposed, including warm dark matter (WDM; e.g., Di Paolo et al. 2018), self-interacting DM (Spergel & Steinhardt 2000), and ultra-light axions (ULAs; e.g., Tulin et al. 2013); moreover, the possibility that the dark particles gain energy from the standard model particles by means of feedbacks, that is, by sudden gas outflows into the galaxy halo driven by supernovae, raises doubts on the collisionless status of dark particles in the AC/DM scenario (e.g., Governato et al. 2012).

Although the cored density distribution is often considered as preponderant in disk systems, a complete and comprehensive comparison between the galaxy kinematical data and the NFW halo profile has not been carried out so far. The notable questions even in disk systems are (i) the degree of the disagreement of data with simulations as a function of the galaxy reference velocity (Vopt) and of its Hubble type, and (ii) the way in which this discrepancy can be qualitatively characterized in general and in the various different objects.

The results found in this work are a necessary first step to answer these questions. In this regard, we stress that we tested the NFW profile not only by determining whether it reproduces the kinematics of disk systems, but also by verifying whether the resulting best-fit models (i) reproduce the relationship between two profile parameters, that is, concentration (c) and virial mass (Mvir), that emerges from N-body simulations; and if they (ii) lead to fractions of dark matter in systems of different virial masses that agree with independent measurements.

Only a complete assessment of the actual inability of the virialized noncollisional matter to describe the actual density halos around galaxies can shed light on how the collisionless scenario may be changed properly. The processes within a collisionless particle scenario include adiabatic contraction, feedback from supernovae, and clump migration (see, e.g., Blumenthal et al. 1986; El-Zant et al. 2016; Macciò et al. 2012; Di Cintio et al. 2014). Moreover, newly proposed scenarios for the DM particles do not always produce cores. For instance, the ULAs scenario seems to form core radii in the DM halos with M < 10¹¹ M⊙ (e.g., de Martino et al. 2018); in the baryonic feedback scenario, the DM halos retain their cuspy profiles if Mstellar/Mhalo < 0.001 or Mstellar/Mhalo > 0.005; and in WDM scenario, it is difficult to explain cores in the halo densities of dwarf galaxies (e.g., Salucci 2019).

Furthermore, we also exploit the fact that the luminous and dark masses of galaxies can be determined by methods alternative to the RC analysis and then compared with those obtained from the RC analysis. In detail, disk masses can be derived by multiplying the galaxy luminosities with their mass-to-light ratios estimated from their colors, while the virial masses are obtained by means of weak-lensing measurements (e.g., Reyes et al. 2012; Mandelbaum et al. 2016) or from the abundance-matching method (e.g., Moster et al. 2013; Shankar et al. 2006; Rodriguez-Puebla et al. 2012).

We assume Ω_0 = 1; Ω_matter = 0.3; Ω_baryonic = 0.04; Ω_DM = 0.26; Λ = 0.7 and H₀ = 72 km s⁻¹ Mpc⁻¹.

The structure of this paper is as follows: in Sects. 2 and 2.1, we describe the samples we used. In Sect. 2.2 we review the process of coaddition of individual RCs, and in Sect. 2.3 we discuss the mass modeling, which includes the disk and halo components. In Sect. 3 we obtain the mass model of 26 coadded RCs and discuss their implications, in particular, the implications from the resulting best-fitting values of the model-free parameters, MD, Mc, and c. Finally, we draw conclusions in Sect. 4 based on our results.

2. Samples and mass model

2.1. Sample

The 26 coadded RCs that we obtained from more than 3200 individual RCs of disk systems and that we discuss in Sect. 2.2 belong to four samples: Persic et al. (1996), Catinella et al. (2006), Di Paolo et al. (2019), and Karukes & Salucci (2017). These coadded RCs have never been used for the goal of testing NFW profile. 900 RCs in Persic et al. (1996) were also independently analyzed by Catinella et al. (2006). (i) In the first sample, optical RCs out to ~1.2 Ropt are combined with HI RCs out to 2 Rvir, where Ropt is the optical radius and defined as the radius enclosing 83% of the total stellar mass of a galaxy. (ii) The second sample is composed of optical RCs alone. (iii) The third and the fourth samples consist of a combination of about 90% optical RCs and 10% HI RCs. Then, the innermost region (R < 2/3 Ropt) of almost all the 3200 galaxies are traced by high-resolution optical RCs. In short, each coadded RC is obtained from a large number of measurements, all of which belong to RCs of galaxies of same Hubble type and with similar values of Vopt, which is the velocity at the optical radius (Ropt). Moreover, they have a very high spatial resolution, so that they are not affected by the beam-smearing effects that may distort the inner profile of low-resolution RCs. Finally, all the coadded RCs we used are extended out to at least, R = 3 R₀, where R₀ is the disk scale length. This is discussed in Sect. 2.2.

The first sample has been published in Persic et al. (1996, hereafter PSS96). It consists of ~900 individual RCs, arranged into 11 M₁ (the I-band absolute magnitude bins), whose central values span from ~17.5 to ~23 (which corresponds to 75 km s⁻¹ to 279 km s⁻¹), and which yield 11 coadded rotation curves built by arranging the RCs in their corresponding M₁ bins. In radial normalized coordinates x ≡ R/Ropt, the radial bins have a size of ~0.1.

The second sample comes from Catinella et al. (2006, hereafter Ca06; see also Lapi et al. 2018), and it consists of ~2200 individual RCs that also include the PSS96 sample. Individual RCs are arranged into nine optical velocity bins, whose central values span from 104 km s⁻¹ to 330 km s⁻¹, and the normalized radial bin has a size of 0.06.

The third sample, from Di Paolo et al. (2019, hereafter LSB), consists of 72 low surface brightness galaxies with velocities at the optical radius Vopt spanning from ~24 km s⁻¹ to ~300 km s⁻¹. They are arranged into five optical velocity bins whose central values are given in Di Paolo et al. (2019) and whose normalized radial size is ~0.1.

The fourth sample, from Karukes & Salucci (2017, hereafter KS17), consists of 36 RCs of dwarf irregular galaxies arranged into one velocity bin whose optical velocities Vopt span from 17 km s⁻¹ to 61 km s⁻¹. Its central value is (Vopt) = 40 km s⁻¹, and the normalized radial average size of each bin is ~0.1.

Samples 1 and 2 therefore include similar objects (normal spirals), and the second sample acts as an independent verification of the first. Samples 3 and 4 include peculiar disk systems (low surface brightness and dwarf disks). The LSB sample is an
environment extremely useful for investigating dark matter. The disk components of LSBs have a much lower surface density than normal spirals. The dwarf disks are objects with the smallest disks.

The PSS96 and Ca06 samples include about 90% of the objects belonging to Sb-Im Hubble types. Both samples have galaxies with \( V_{\text{opt}} \) in the range of normal spirals and are much larger than those in the KS17 sample. The LSB includes only low surface brightness objects, which in turn are almost entirely missing in the previous three samples.

**2.2. Coadded rotation curves**

It is well known that each disk galaxy has two tags (properties) that specify it completely: (i) \( R_D \) the size of the stellar disk that is derived by its surface luminosity profile. In these objects it is reasonable to assume that (Freeman 1970)

\[
I(R) = I_0 e^{-\frac{R}{R_D}}.
\]

\( I_0 \) is the central surface luminosity, \(-100 \, L_{\odot} \, pc^{-2} \), and \( R_D = 1/1.67 \, R_{1/2} \) is the scale length that determines the distribution of stars in the galaxy disk, while \( R_{1/2} \) is the half-light radius. The photometric quantity \( R_D \), analogous to the well-known half-light radius \( R_{1/2} \) in ellipticals (e.g., Salucci 2019), is related to the scale length of the Freeman disk by

\[
R_D = 3.2 \, R_{D}.
\]

Thus, for exponential thin disks: \( R_D = 3.2/1.67 \, R_{1/2} \); moreover, \( R_{\text{opt}} \) and \( R_D \) are physically identical. We stress that in the case of stellar disks with (usually mildly) nonexponential profiles, \( R_{\text{opt}} \) also still marks the dynamical edge of the disk as the quantity \( 3.2 \, R_D \) in the case of Freeman disks.

(ii) Disk galaxies include irregular spirals, dwarf irregular disks and low surface brightness disks in addition to normal spirals. These types of objects are all rotationally supported, but have very different photometric properties (see Salucci 2019) and therefore are different probes for the distribution of dark matter. We specify that for a given \( R_D \), the disk mass can vary largely, depending on the morphological type.

We can represent all the rotation curves of disk systems by means of a universal profile (e.g., Salucci et al. 2007). In detail, the universal RC (URC) is obtained from thousands of individual RCs when they are arranged in a number of coadded rotation curves. The uncertainties of coadded (stacked) rotation curves are significantly smaller than those of the individual RCs. Moreover, these coadded curves are as extended as the most extended individual RCs: \( x_{\text{outermost}} > 5 \, R_D \), where \( x_{\text{outermost}} \) is the center of the outermost radial bin in each coadded RC and has a very high spatial resolution (<1/4 \( R_D \)). The process of building such curves is explained in detail in the original works, but we briefly recall it here.

The basic assumption underlying the coaddition process and verified in disk systems is that the galaxies with similar \( V_{\text{opt}} \) \( \equiv V(R_{\text{opt}}) \) (that also have similar \( R_{\text{opt}} \)) have similar rotation curves, especially when the latter are expressed in the normalized radial coordinate \( x \equiv R/R_{\text{opt}} \) (Yegorova & Salucci 2007; Gammaldi et al. 2018; López Fune 2018; Rhee 1997). This leads to similar mass distributions, with the DM density always taken as a cored distribution.

The concept of coadded RCs, implicit in Rubin et al. (1985), which was pioneered by Persic & Salucci (1991), set by Persic et al. (1996), and extended to large galactocentric radii and different Hubble types by Salucci et al. (2007), Di Paolo et al. (2019), and Karukes & Salucci (2017) allows us to derive \( V_{\text{coadd}}(R/R_{\text{opt}}, M_I) \) or \( V_{\text{coadd}}(R/R_{\text{opt}}, V_{\text{opt}}) \), that is, the average (coadded) RCs of galaxies with the magnitude lying in a bin centered at the \( J \)-band absolute magnitude \( M_J \) and of size \( \delta M_J \) (or centered at \( V_{\text{opt}} \) and of size \( \delta V_{\text{opt}} \)). The number of objects and the position and size of each magnitude (or velocity) bin are indicated in detail in the original works.

The coadded RCs were built in three steps in a process that is similar to the process used in cosmological numerical simulations to work out the averaged DM density distribution of halos of similar virial mass \( M_{\text{vir}} \) (see: Navarro et al. 1996). We describe here the details for one of the four samples we used (PSS96); the procedure is only marginally different from those adopted for the other three samples.

(i) The whole \( J \)-magnitude range is divided into 11 successive bins, each of which is centered at \( M_J = J \ldots 11 \) and has a size \( \delta M_J \). The 11 values of the latter quantities, alongside with the 11 values of \( V_{\text{opt}}, R_{\text{opt}} \), are given in Table 1 (also in Persic et al. 1996). The rotation curve \( V_{\text{opt}} \) of the sample assigned to its corresponding \( J \)-magnitude bin is normalized by its \( V_{\text{opt}} \) value. Next, by using the known galaxy value of \( R_{\text{opt}} \), each RC is expressed in terms of its normalized radial coordinate \( x_{\text{j}} \equiv R/R_{\text{opt}} \). Here, \( j \) is the index of the magnitude (velocity) bins, \( j_k \) is the index of the various galaxies in the above bins before coaddition, \( j_k \) is the index of the radii at which \( j \)-coadded RC have measurements. We directly determined in the first sample (PSS96) the various \( R_{\text{opt}} \) from the definition, for LSB and KS17, the Freeman disk is an excellent distribution for their stellar content, and this also holds for the spirals in Ca06, if slightly less so. In the above works, the \( R_{\text{D,j}} \) values were used to derive \( R_{\text{opt}} \) from Eq. (2). In this way, every RC of our sample was then double-normalized and tagged as

\[
v_{\text{jk}}(x_{\text{jk}}) \equiv \frac{V_{\text{jk}}(x_{\text{jk}})}{V_{\text{jk, opt}}},
\]

Let us notice that \( V \) is velocity in physical units while \( v \) is double-normalized velocity. (ii) Each of the \( N_j \) double-normalized individual rotation curves \( v_{\text{jk}} \) in each \( j \) bin was binned into 20 radial bins of length 0.1 and index \( j_i \), and the number of data \( N_{ji} \) was then averaged to obtain the double-normalized coadded RCs and their uncertainties computed from their rms \( \delta V_{\text{coadd}}(x_{\text{jk}}, M_J,j) \) and \( N_{ji} \): \( \delta V_{\text{coadd}}(x_{\text{jk}}, M_J,j)/((N_{ji} - 2)^{1/2}) \).

(iii) The final step is that the double-normalized curves are denormalized using the averaged values of \( V_{\text{jk, opt}} \) and \( R_{\text{jk, opt}} \).

In general, the extension of the 26 coadded RCs is \( x_{\text{outermost}} = 1.75 \pm 0.25 \) and the positions of the various \( x_{\text{jk}} \) are given in the table available at the CDS for \( j = 1 \ldots 26 \). For \( x > 2.6 \), the concurring RCs are mostly HI RCs. We recall that Persic et al. (2004) have shown that HI and optical RCs describe the same gravitational potential. Noticeably, these coadded curves vary very little: almost always, \( \delta V_{\text{coadd}} \leq 0.03 V_{\text{coadd}} \) (e.g., Salucci 2019) because for most of the radial bins in each coadded RC, we have many measurements, from 20 to 200. When these are averaged, the statistical component of the variance in the velocity measurements is much reduced. Furthermore, \( v_{\text{jk}}(x_{\text{jk}}, M_J,j) \), the individual double-normalized RCs of objects with the same magnitude \( M_J \) are all very similar.

It is also important to stress in reference to all samples (with \( j = 1 \ldots 26 \)), that in each of the \( j \) luminosity (velocity) bins, the values of the normalization velocities \( V_{\text{jk, opt}} \) of the individual RCs assigned to the \( j \) bin are very similar. They each differ from the averaged bin value \( V_{\text{opt}} \) by less than 10%. For simplicity of
model including a cored DM halo with perfectly fit by this function, that is, in more detail, by a velocity we have shown that all the 26 coadded RCs that we used here, are URC provides a crucial model comparison. In previous works, matter halo (Burkert 1995; Persic et al. 1996). In this work, the velocity coming from a Freeman stellar disk and a Burkert dark sen as the sum in quadrature of the components to the circular (1996) and in the others in the subsequent works. It was cho-

\[ V \delta x = \frac{\rho_0}{(R/r_s)(1 + R/r_s)^2}, \]  

where \( R \) is the radial spherical coordinate, and \( \rho_0 \) and \( r_s \) are the characteristic density and the scale radius of the dark halo. It is useful to define the concentration \( c \equiv R_{\text{vir}}/r_s \), where \( R_{\text{vir}} \) is the virial radius given by \( M_{\text{vir}} \equiv 4/3\pi 100\rho_0 r_s^3 \). The critical density is \( \rho_{\text{crit}} = 3H_0^2/(8\pi G) \) with \( H_0 \) the current value of Hubble’s parameter. We assume \( H_0 = 72 \text{ km s}^{-1} \text{Mpc}^{-1} \). No
result of this paper changes by assuming the lower value of $H_0 = 67$ km s$^{-1}$ Mpc$^{-1}$ favored by Planck CMB measurements (Planck Collaboration VI 2020).

In the circular velocity model, the contribution of the DM halo to the circular velocity adds in quadrature to that of the stellar disk as

$$V^2_{\text{mod}}(R) = V^2_D(R) + V^2_{\text{NFW}}(R),$$

where $V_D$ and $V_{\text{NFW}}$ are the contribution of the stellar Freeman disk and the dark halo, respectively. In the disk systems we consider in this work, the stellar component is described by an exponential Freeman disk (see Freeman 1970) with a surface density given by

$$\Sigma_D(R) = \frac{M_D}{2\pi R_D^2} e^{-R/R_D} = \left[ \frac{M_D}{2\pi(R_{\text{opt}}/3.2)^2} \right] e^{-3.2R/R_D}.$$

Its contribution to the circular velocity is

$$V_D^2(x) = \frac{1}{2} \frac{GM_D}{R_D} (3.2x)^2 \left[ I_0(1.6x)K_0(1.6x) - I_1(1.6x)K_1(1.6x) \right],$$

where it is worth recalling that $M_D$ is the disk mass, $x = R/R_{\text{opt}}$ and $I_n, K_n$ are the modified Bessel functions of nth order.

The dark halo contribution to the circular velocity $V^2_{\text{NFW}} = G M_{\text{NFW}}(R)/R$ that we investigate here is the contribution generated by the NFW dark halo density profile ($\rho_{\text{NFW}}$) and is given by

$$V^2_{\text{NFW}}(R) = \frac{GM_{\text{vir}}}{R} \left( \ln(1+c) - \frac{c}{1+c} \right),$$

where $M_{\text{vir}}$ is the halo virial mass, $c = R_{\text{vir}}/R$ is the normalized radial coordinate, and $c = R_{\text{vir}}/r_e$ is the concentration parameter.

The velocity model that we tested with 26 coadded rotation curves obtained from more than 3200 individual RCs that consist of more than 10 independent kinematical measurements is

$$V^2_{\text{mod}}(R; M_D, c, M_{\text{vir}}) = V^2_D(R; M_D) + V^2_{\text{NFW}}(R; c, M_{\text{vir}}).$$

The notation $(c, M_D, M_{\text{vir}})$ has to be considered as a 26×3 matrix.

Finally, we stress that we did not test an empirical dark matter density profile (as in Burkert 1995) for which we would need data out to the galaxy virial radius to prove its success, but a theoretical profile obtained from $N$-body simulations in the

---

Table 1. Values of the best-fit parameters of the mass modeling with their 1σ uncertainties for the PSS96 sample.

ACDM scenario, whose functional form is believed to be perfectly known from $r = 0$ to $r = R_{\text{vir}}$. In detail, the two free parameters $\rho_0$ and $r_s$ can be derived by the inner regions of the RCSs, that is, for $R < r_s$ (see Eq. (6)). We do not need very extended kinematics to disprove the presence of an NFW halo. It is clear that with more external data the estimate of these parameters may change, but our aim is not to show a global failure of the NFW + disk model but only its extremely serious troubles in the region in which the model-independent analysis of RCSs has revealed DM density cores, that is, for $r < r_0 \sim r_s$. We did not investigate whether for $r > R_{\text{opt}}$ the DM halo density converges to an NFW, as it appears to do in spirals (Salucci et al. 2007).

### 3. Results

The data fitting was performed by means of the nonlinear least-square method ($\chi^2$-Levenberg-Marquardt method). We fit each coadded rotation curve with the above model. The $\chi^2$ statistic is defined as

$$\chi^2_j = \sum_{i=1}^{N_p} \left( \frac{V_{ji,\text{coadd}} - V_{ji,\text{mod}}(X)}{\sigma_{ji,\text{coadd}}^2} \right)^2.$$  

where $V_{ji,\text{coadd}}$ is the value of coadded RCS at $x_j$ tagged as $j$; same definition stands for $\sigma_{ji,\text{coadd}}$ and $V_{ji,\text{mod}}$ that are the observational uncertainties of the $j$ coadded RCS value at $x_j R_{\text{opt}}$, and the corresponding model value, respectively. $N_j$ are the number of kinematical measurements of each coadded RC (see Tables 1–3), and $X$ is the set of three free parameters of the model, $X = (M_D, M_\text{int}, c)$, which are to be determined through the fitting procedure. The values of $R_{\text{opt}} = x_j R_{\text{opt}}$, $V_{ji,\text{coadd}}$, and $\sigma_{ji}$ are given in the table available at the CDS.

These best-fit values and those of the reduced $\chi^2_j$ ($\chi^2_{\text{red},j}$), where $\chi^2_{\text{red},j} = \chi^2_j/(N_j - 3)$ and the denominator is the number of degrees of freedom of the model, are shown in Tables 1–3 for the 25 coadded RCSs investigated here. In Fig. A1 we show the triangular plots for 25 mass models.

The coadded RC of KS17 has been modeled in the original paper, where the authors found

$$\log M_{\text{vir}} = 11.68 \pm 0.87, \quad c = 4.73 \pm 3.19, \quad \log M_D = 2.5^{+2.5}_{-2.0},$$  

with $\chi^2_{\text{red}} \approx 12$.

At this point, we state that in order to reclaim success, we expect from the model under investigation that it fits the data perfectly.
we find that this quantity exceeds the value of 1.4 in 16 cases. The cosmic variance in log $c$ is 0.1 dex, which is negligible for the aim of our work. Figure 3 shows the $c$–log ($M_{\text{vir}}$) relation of our 26 coadded fits with their corresponding uncertainties. We can easily realize that most of the best-fit values lie very far from the Eq. (13) relation, of which they are unable to trace even the gross trend.

Another scaling relationship of great importance is the disk mass $M_D$ versus virial halo mass $M_{\text{vir}}$; noticeably, this relation can be independently derived by the abundance-matching method (e.g., Moster et al. 2010). We find

$$
\frac{M_D}{M_{\text{vir}}} = A \left( \frac{M_{\text{vir}}}{M_1} \right)^{-\beta} \left( \frac{M_{\text{vir}}}{M_1} \right)^{\gamma},
$$

(14)

where $M_1, A, \beta,$ and $\gamma$ are

$$
\log M_1 = 11.884; \ A = 0.0564; \ \beta = 1.057; \ \gamma = 0.556.
$$

(15)

A completely independent analysis has yielded the disk mass $M_D$ versus virial halo mass $M_{\text{vir}}$ (see Shankar et al. 2006). This is just mildly different from the mass in Eq. (14), also considering that both have an uncertainty of 0.2 dex in log ($M_D$).

$$
M_D = 2.3 \times 10^{10} M_1 \left( \frac{M_{\text{vir}}}{3 \times 10^{12} M_1} \right)^{3.1} + \left( \frac{M_{\text{vir}}}{3 \times 10^{12} M_1} \right)^{2.2},
$$

(16)

which we also included in the comparison with the best-fit values of the model under investigation. The stellar-halo mass relationship so obtained is shown in Fig. 4, along with the above independent relationships (14) and (16). It is evident that most of the values of the (NFW + stellar disk) model lie very far from...
either relation. The results of KS17 are entirely inconsistent with the observational relations.

The poorest performance of the model under study is probably related to the fact that this never shows a halo mass with \( M_{\text{vir}} < 10^{12} \) \( M_\odot \). Halo masses like this are known to exist in a great number in the ΛCDM scenario.

The failure of the model under analysis to reproduce the kinematics of spirals is summarized in Tables 1–3 and Figs. 3 and 4. In order to have a more complete view of the problem, we plot the values of three important structural parameters derived from the best fits of the 26 coadded RCs: in Fig. 5 we show \( c \) as a function of log \( (M_D/M_{\text{vir}}) \) and \( \chi^2_{\text{red}} \). The two surfaces restrict the volume in which we expect the values of the DM parameters to lie in, which means that the ΛCDM NFW model would be a valid representation of the 26 coadded RCs. Each sphere tags the best-fit model of a coadded RC. We realize a large failure of the NFW density profile. Nearly all of the coadded RCs lie far outside of the goal volume.

We now discuss the other two minor, but cosmologically important components of baryonic matter in disk systems. A bulge contribution to the circular velocity is present in (only) disk galaxies with the highest stellar mass. In Appendix B we include this component in the circular velocity model of the coadded RCs relative to these objects. We find that the resulting best-fit model agrees well with that obtained from Eq. (10). The other component is a gaseous HI disk in the outermost parts of the least luminous objects. In Appendix C we present the model for the coadded RCs of the latter. We add an HI gaseous disk contribution and compare the resulting best-fit model with that of Eq. (10). We find a good agreement in this case as well. This shows that including these two minor baryonic components does not change the results of this work.

It is important to compare the results of our work with a previous study of individual RCs (Korsaga et al. 2019b). It is worth noticing that the coadded RCs with respect to the individual RCs show on average higher values of \( c \) and a stronger correlation with the halo mass as likely expected by the coaddition process, which has eliminated a part of the random errors of the individual RCs. In Fig. 6 we plot our 26 \( c \) versus \( V_{\text{opt}} \) along with those obtained from individual RCs in Korsaga et al. (2019b). The agreement further reinforces the statement of the gross inability of NFW halos to reproduce the observed disk kinematics.

4. Conclusion

More than 3200 RCs of disk systems with different \( V_{\text{opt}} \), ranging from 20 km s\(^{-1}\) to 330 km s\(^{-1}\), were stacked into 26 coadded RCs that extended out to \( R_{\text{opt}} \) and beyond. These data represent the whole kinematics of disk systems well and were used to investigate a particular mass distribution. This is characterized by a dark halo with an NFW profile and a stellar Freeman exponential thin disk. The model has three free parameters: the disk mass \( M_D \), the halo virial mass \( M_{\text{vir}} \), and the halo concentration \( c \). These were derived by means of best-fitting the coadded RCs. Because the NFW velocity model is an analytical model that is valid from \( r = 0 \) and \( r = R_{\text{vir}} \), we can derive all the related \( \rho_c, r_s \), and \( R_{\text{vir}} \) from the two halo parameters above.

The aim of our investigation was to determine whether dark halos around spirals possess cuspy inner profiles. The outcomes crucially add to the results that were obtained in the past 20 years by means of the analysis of several dozen individual RCs. Although these have given an unequivocal answer against this possibility, they cannot be considered either entirely unbiased or complete.
By means of the above 26 coadded RCs we have completed the investigation about the core-cusp question in disk systems of any morphology and luminosity (mass). We found that generally, the model under investigation fails to reproduce the observational data. Not only does it fit the coadded RCs poorly, implying high values for $\chi^2_{red}$, but in many cases, the best-fit values of the structural parameters $c$, $M_{vir}$ and $M_D$ are also very different from the expectations from simulations and from measurements independent of RCs data. Noticeably, the model fails at any reference velocity from ($V_{opt} = 20\, \text{km s}^{-1}$) to ($V_{opt} > 300\, \text{km s}^{-1}$). One exception may be for objects with $190\, \text{km s}^{-1} \leq V_{opt} \leq 210\, \text{km s}^{-1}$, for which the model appears to perform as well as the Burkert cored halo + Freeman disk model; in this case, only individual HI RCs with the optical velocity in this range and with very much extended kinematics can solve this riddle (Karukes & Salucci 2017). We stress that according to our results, we conclude that within the LCDM scenario, the corification of initial cusps must occur in the smallest and largest disk systems.

A detailed investigation shows that the failure of the model has different aspects: the concentration $c$ takes a wide range of values from 1.5 to 28.3 that is well outside the range found in simulations. The dark matter halo masses in the 50% of the cases reach implausibly high values. In some cases, the values of the disk masses are ridiculously low. The $\chi^2_{red}$ value, on the other hand, can be acceptable for only 38% of the cases.

From the best-fit parameters we reconstructed the model scaling relations $c-M_{vir}$ and $M_D-M_{vir}$ that emerge to clearly contradict those obtained from observations and from $N$-body simulations (Salucci et al. 2007; Shankar et al. 2006; Bullock et al. 2001). The 3D relation of $c-M_{D}/M_{vir}=\chi^2_{red}$ in Fig. 5 clearly shows that most of the best-fit values lie outside the volume that indicates a successful representation of the kinematics of disk galaxies.

This result may be gauged by the fact that, in previous works, we found that the cored halo + Freeman disk is able to reproduce all these 26 coadded RCs with very low $\chi^2_{red}$ values ($\sim 1$) and yields meaningful relations among the model structural parameters (see Karukes & Salucci 2017; Lapi et al. 2018; Di Paolo et al. 2019). In this work, however, we make no claim about (i) the LCDM scenario, in that cores in the DM density might be produced during the cosmological evolution of galaxies, (ii) the DM distribution at large radii $r > 100\, \text{kpc}$, in galaxies of other Hubble types, in spirals at high redshifts $z > 0.5$, and in disk systems just after their formation for the evident lack of available measurements. Only a large number of high-quality individual RCs, that is, 100 per magnitude, per Hubble type, per 0.5 redshift can resolve all these questions.

Acknowledgements. We thank the referee for suggestions that have improved the quality of the paper and Chiara Di Paol for useful discussions.

Appendix B: Bulge contribution to the rotation curves of disk systems

The largest disk galaxies with $V_{\text{opt}} > 220 \text{ km s}^{-1}$ have an additional inner stellar component, a bulge. The rotation curve of these systems is then composed of a spherical bulge, a disk, and a dark halo,

$$V^2(R) = V^2_B(R) + V^2_D(R) + V^2_{\text{NFW}}(R),$$

where $V_D$ and $V_{\text{NFW}}$ are the disk and dark halo components of the rotation curve, respectively, and are defined in Eqs. (8) and (9). $V_B$ is the bulge contribution. This component is smaller than the stellar disk by at least a factor of 3. We assumed that we can represent this component by the following velocity profile:

$$V^2_B(R) = \frac{GM_B}{R} \left(\frac{x^2}{0.12^2 + x^2}\right),$$

where $M_B$ is the bulge mass. In the above, the bulge behaves like a point mass at large distances, for $R \ll 1/3 R_D$, it increases like $R^2$.

The velocity model therefore has four free parameters. Table B.1 shows the best-fitting results for the most massive bins of the three samples Ca06, PSS96, and LSB where this component is (mildly) relevant. The corresponding RCs are shown in Fig. B.1. The bold and red values are the same as in Tables 1–3. We realize that including the very central bulge does not change the results of this work. It is worth noting that we did not investigate the bulge-dominated Sa spirals here.

Table B.1. Values of the best-fit parameters of the mass model along with their 1σ uncertainties.

| Sample | $R_{\text{opt}}$ | $V_{\text{opt}}$ | $c$ | log($M_B$) | log($M_D$) | log($M_{\text{vir}}$) | $\chi^2_{\text{red}}$ |

Notes. Column (1) lists the sample name, Col. (2) the optical radius, Col. (3) the optical velocity, Col. (4) the concentration, Col. (5) the bulge mass, Col. (6) the disk mass, Col. (7) the halo mass (virial mass), and Col. (8) the reduced $\chi^2$ value.
Fig. B.1. Observed and fit RC modeling: The components of the NFW dark halo (green dashed), disk (dot-dashed red), and bulge (dashed black) that contribute to the total rotation curve and the observed data (red circles) with error bars are shown in the left panels. Their corresponding triangle plots of the 2D invariance between parameters with $1\sigma$ uncertainty are shown in the right panels.
Appendix C: Gas contribution to the rotation curves

Disk galaxies also receive an HI contribution to their circular velocities. We did not consider this here because (i) this component is relevant only in small objects and outside $R_{\text{opt}}$, (ii) in any case, the effects of incorporating this gaseous component results in NFW cusps that are even more unlikely (e.g., Di Paolo et al. 2019; Karukes & Salucci 2017).

In this section we add these component to the stellar disk + NFW halo model to the circular velocity of galaxies for the lowest velocity bins of our sample. The HI surface density can approximately be reproduced by a Freeman distribution with a scale length $R_{\text{HI}}$ that is about three times larger than that of the stellar disk (see Evoli et al. 2011; Wang et al. 2014). We then take for the contribution of the HI disk to the circular velocity

$$V_{\text{HI}}^2(R) = \frac{G M_{\text{HI}}}{6 R_{\text{D}}} [1.07 x]^2 [I_0 K_0 - I_1 K_1],$$

where $x = \frac{R}{R_{\text{opt}}}$ and $M_{\text{HI}}$ is the mass of HI disk, considered as a free parameter as $M_{\text{D}}$ and $I_n$ and $K_n$ are the modified Bessel functions calculated at $0.53x$. The expected range of the free parameter values of the stellar+ gaseous disk and the dark halo are reported in Table C.1, and the mass model best-fitting result is shown in Fig. C.1. Compared to the results we obtained when we neglected the gas contribution (see Fig. A.1), it produces only a mild difference in the mass model when we include the gas.

| Free parameter | Range of values |
|----------------|-----------------|
| $\log(M_{\text{D}})$ | 8–9 |
| $\log(M_{\text{vir}})$ | 12.5–13.5 |
| $c$ | 0.5–2 |
| $\log(M_{\text{HI}})$ | 8.4–9.4 |

Notes. Masses are expressed in solar mass units.
