Soil compaction is one of the major problems faced in modern agriculture (Rücknagel et al., 2015). With heavy rainfall, the associated water saturation of the soil caused by drip irrigation and mechanical rolling will result in soil compaction. Once air capacity decreases and gas exchange is restricted, the physical and chemical properties of soil worsen, which affects the normal growth of the crops, resulting in reduced production (Nawaz et al., 2013). Aeration irrigation is an improvement of SDI, which has been studied for nearly 20 years (Greenway et al., 2013). Aeration irrigation involves the delivery of oxygen or oxygenated material into the root zone of the crop through SDI systems to improve soil aeration and to meet the needs of root growth and development, thereby improving crop yield and quality (Bhattarai et al., 2006; Lei et al., 2015). Recent report on oxygenation irrigation experiments confirmed that using of oxygenated SDI water could increase crop yields, water use efficiency and salinity tolerance, the effect was more significant on heavy clay soils (Abuarrab et al., 2013; Bhattarai et al., 2006, 2008; Ityel et al., 2014). Li et al (2016b) showed that soil aeration enhanced greenhouse tomato plant growth, yield fruit shape, and nutritional quality. Research on capsicum showed that increased oxygen concentration in the root zone by 5% by allowing roots to penetrate into the capillary barrier gravel layer and improved biomass and fruit yield by 16% and 18%, respectively (Ityel et al., 2014). This research showed that aeration irrigation was an efficient technology with a certain application prospect. However, in production, it was found that because of the limited infiltration range of traditional SDI, it was advantageous for annual crops such as tomato, maize, soybean, and chickpea, but there have been relatively few reports on perennial and large root fruit trees.

Ben-Noah and Friedman (2016) found that addition of a perforated sphere around the irrigation aeration dripper promotes significant increases in soil oxygen concentrations compared with direct air injection. This suggests that the efficiency of existing drip irrigation methods could be improved by increasing the efficiency of aeration irrigation. SDI with tanks is a technique newly developed by our research team that can effectively solve the problem of small infiltration range. This new method is suitable for applications in the forestry and fruit industries. Compared with traditional surface drip irrigation, SDI with tanks has the advantages of water savings of more than 30%, promotion of deeper root system growth, improvement of fertilizer utilization, and reduced labor requirement (Yu et al., 2014, 2015). Moreover, this method can be used for aeration without extensive increases in cost.

Materials and Methods

Experimental design. The experiment was conducted from Apr. to Sept. 2016 in a greenhouse (108 m long and 7 m wide) at Shihezi University, located in Shihezi city, Xinjiang Uygur autonomous region, Northwest China (lat. 45°19’N, long. 86°03’E). The temperature range is 17 to 33 °C, and the...
relative humidity is 60% to 80% in the greenhouse during the experiment.

In two treatments, aeration and no aeration (CK), with 15 repetitions, a single ‘Red Globe’ grape cutting seedling was transplanted in each box (Fig. 1). The box length and width were each 40 cm, and the height was 60 cm. The soil was collected from 0 to 20 cm depth of a vineyard with 10 years of planting of ‘Red Globe’ grape in the experimental station and passed through a 40-mesh sieve. When loading, each 10 cm was considered one layer and compacted. After completion of loading, further compaction was performed by irrigation (Zhao et al., 2017). The same amounts of irrigation and the same growth were transplanted in the cultivation box, and the mixing system (LI-COR Inc., Lincoln, NE). Measurement was once every 2 h, and the daily variation was measured on the third and fifth day of the irrigation period. The frequency of the measurement was the same as that of the first time.

Rhizosphere soil respiration. Determination of soil respiration intensity used an LI-8100 open road soil carbon flux measurement system (LI-COR Inc., Lincoln, NE). Measurement time and frequency were in accordance with the pulse-labeling experiment was conducted. At 45 d after aeration treatment, three plants with uniform growth were selected for each treatment. The daily variation was measured on the third and seventh day after irrigation during the same irrigation period. The frequency of the measurement was once every 2 h, and the sequence of measurement was the same as that of the first time.

Measurement Indices and Methods

Rhizosphere soil oxygen saturation. A portable oxygen analyzer was used to measure dissolved oxygen after irrigation, and the oxygen sensor was pushed into the soil at the depth of 0.25 m when measured. At 45 d after aeration treatment, three plants with uniform growth were selected for each treatment. The daily variation was measured on the third and seventh day after irrigation during the same irrigation period. The frequency of the measurement was once every 2 h, and the sequence of measurement was the same as that of the first time.

in the labeled chamber was absorbed by the sodium hydroxide absorption device before marking to improve the absorption and assimilation rate of $^{13}$CO$_2$. The labeling process started at 11:00 AM on a sunny day. CO$_2$ analyzer monitoring marker was used to monitor CO$_2$ concentration. Marking methods as described in An et al. (2015).

After 57 d of aeration treatment, three grape plants were selected for each destructive sampling. The whole plant was divided into old leaves (leaves that had grown before aeration), new leaves (leaves grown after aeration), old branches (branches of the previous year), new branches (branches of this year), fine roots (diameter <2 mm), and thick roots (diameter >2 mm). Sampling methods refer to Zhao et al. (2018). The samples were crushed in a mill and then sifted through a 150-mesh sieve; the samples were then bagged. $\delta^{13}$C value ($\%$o) of bagged samples was measured in the DELTA V Advantage isotope ratio mass spectrometer. The $\delta^{13}$C value ($\%$o) was expressed relative to the Pee Dee Belemnite (PDB) standard: $\delta^{13}$C($\%$o) = ($R_{\text{sample}}/R_{\text{PDB}} - 1$) × 1000, where $R_{\text{sample}}$ is the ratio of $^{13}$C/$^{12}$C in the sample and $R_{\text{PDB}}$ was equal to 0.0112372 (Werner and Brand, 2001).

After 90 d of aeration treatment, five grape plants were selected for each destructive sampling. The sampling method was the same as sample collection of $^{14}$C determination. Plant biomass was determined after drying to constant weight.

Statistical analysis. The data were calculated by Excel 2013, and figures were made using AutoCAD 2007 and SigmaPlot 13.0 software. Data were compared via one-way analysis of variance using IBM SPSS 19.0 software (SPSS Inc., Chicago, IL). 0.05 was considered a significant difference and 0.01 a highly significant difference.

Results

Rhizosphere soil respiration and oxygen saturation. As shown in Fig. 2, the oxygen saturation of soil in the aeration treatment increased first and then decreased on the third and seventh day after irrigation, reaching a maximum at 10:00 AM. The oxygen saturation in the CK was relatively stable during the diurnal variation. Throughout the diurnal variation process, the oxygen saturation in the rhizosphere of the aeration treatment was higher than that of the CK treatment, and significantly higher at 10:00 AM, 12:00 PM, and 2:00 PM ($P < 0.05$).

The variation trend of soil respiration intensity on the third and seventh days after irrigation was consistent. The variation trend of soil respiration intensity in the aeration treatment at first descended then decreased rapidly, becoming lowest at 10:00 AM; that in the CK treatment showed a trend of increasing and then decreasing during the diurnal variation (Fig. 2). The soil respiration intensity of the CK treatment was higher than that of aeration treatment at 10:00 AM and 12:00 PM. After that, the soil respiration intensity of aeration treatment increased rapidly, and it was significantly higher than that of CK treatment at 2:00 PM and 4:00 PM ($P < 0.05$).

The oxygen saturation in the rhizosphere was $\approx 0.5$ mg·L$^{-1}$ on the third day after irrigation, and it was $\approx 0.6$ mg·L$^{-1}$ on the seventh day after irrigation. The soil respiration intensity was in the range of 5.0 to 8.0 mmol·m$^{-2}$·s$^{-1}$ on the third day after irrigation, and it was in the range of 3.0 to 6.0 mmol·m$^{-2}$·s$^{-1}$ on the seventh day after irrigation (Fig. 2).

Rhizosphere soil microbial community composition. The relative abundance of dominant phyla of the bacterial and fungal communities varied between the two treatments. Proteobacteria, Actinobacteria, Gemmatimonadetes, Acidobacteria, and Planctomycetes were the five most abundant phyla across all samples and accounted for 75.8% of the total bacterial sequences. The most abundant phyla, the aeration treatment had little effect on the community composition, except for Planctomycetacia with aeration treatment, which was significantly lower than that without aeration treatment (Fig. 3A).

We further analyzed the differences in different bacterial classes and found that the relative abundance of Cytophagia and Nitrospira was higher at a soil depth of 20 to 30 cm in the aeration treatment compared with that in the CK treatment (Fig. 4). Specifically, the relative abundance of Cytophagia was significantly enhanced by 27.3%, and the relative abundance of Nitrospira was significantly enhanced by 25.8%.

For fungal phyla, Ascomycota and Basidiomycota were most abundant, accounting for 91.3% and 5.5%, respectively. Interestingly, compared with soil at soil depths of 20 to 30 cm and 40 to 50 cm in the CK, the relative abundance of Ascomycota increased significantly in the aeration treatment, whereas the relative abundance of Basidiomycota decreased at different soil depths in the aeration treatment (Fig. 3B).

Key rhizosphere soil bacterial genera and fungal genera. As shown in Table 1, the proportion of Pseudomonas and Bacillus associated with phosphorus and potassium metabolism with aeration treatment at soil depths of 20 to 30 cm and 40 to 50 cm was higher than that with CK treatment, and the difference was significant ($P < 0.05$). For fungal genera, the proportion of Aspergillus associated with phosphorus metabolism was at soil depths of 0 to 10 and 40 to 50 cm, with aeration treatment significantly higher than CK treatment ($P < 0.01$). Fusarium associated with OM decomposition at different soil depths was significantly higher than that with CK treatment ($P < 0.01$).

Biomass accumulation and distribution. The biomass of the new leaves and fine roots (<2 mm) treated with aeration was 35.82% and 83.74% higher than that of the CK treatment, and the difference reached extremely significant level ($P < 0.01$). The biomass of new branches with aeration treatment was 24.56% higher significantly than that with the CK treatment ($P < 0.05$) (Table 2). For old leaves, old branches, and thick roots (>2 mm), there was no significant difference between the aeration and CK treatments ($P > 0.05$). These results show that the aeration treatment could significantly promote the growth of the new parts of the grape plants.

After pulse labeling, the $^{13}$C fixed by photosynthesis was transferred and distributed in all parts of grape seedlings. The $\delta^{13}$C value of new branches and fine roots (<2 mm) with aeration irrigation was 163.37% and 118.05%, respectively, and was extremely significantly higher than that of the CK treatment ($P < 0.01$). That of thick roots with aeration irrigation was 54.23% significantly higher than that of the CK treatment ($P < 0.05$). The $\delta^{13}$C value of new leaves and old leaves was significantly lower than that of the CK treatment ($P < 0.05$). These results indicate that aeration irrigation can promote photosynthesis and the distribution and transport to new branches and roots.

Contents of C, N, P, K, and C/N in Different Organs of ‘Red Globe’. As shown in Table 3, the carbon content of new leaves and fine roots in aeration treatment was lower than that of CK treatment, and the carbon content of fine roots was significantly different ($P < 0.05$). The nitrogen, phosphorus, and
potassium contents in fresh leaves were 25.94%, 18.56%, and 15.13% higher than those in leaves of CK ($P < 0.05$), respectively, and the nitrogen, phosphorus and potassium contents in fine roots were 8.27%, 9.10%, and 12.12% higher than those in CK ($P < 0.05$). For the total content of P and K, it can be seen that new leaves and fine roots of aeration treatment was significantly higher than that of CK ($P < 0.01$). The C/N of new leaves and fine roots was significantly lower than that of CK treatment ($P < 0.05$; Table 3).

Discussion

Aeration irrigation can increase the oxygen content of the soil (Greenway et al., 2006; Ityel et al., 2014). Ben-Noah and Friedman (2016) found that adding a perforated sphere around the irrigation dripper promoted significant increases in soil oxygen content compared with direct air injection. In the current study, the soil oxygen saturation was significantly improved with the tank, especially within 4 hours after aeration treatment (Fig. 2). Hou et al. (2016) showed that aeration irrigation can increase soil respiration and promote the volatilization of soil CO$_2$, but in our study, the soil respiration intensity of the aeration treatment was lower than that of CK treatment from 10:00 AM to 12:00 PM after aeration treatment, due to aeration treatment promoting the exchange of gas in the root zone soil and decreasing the CO$_2$ content of soil in the root region. After that, the soil respiration intensity of the aeration treatment increased rapidly; this result is consistent with Hou et al. (2016).

Soil bacteria are an important component of soil microorganisms. Most of the dominant bacteria are basically consistent in the soil and include $\approx$10 bacterial groups (Philippot et al., 2010). Phylum abundance analysis revealed that Proteobacteria, Actinobacteria, Bacteroidetes, and Acidobacteria were the top bacterial phyla in all soil samples, with some variation in relative abundance. This finding was similar to the results of Sun et al. (2014). After treatment for 90 d, the soil with aeration treatment at the same depth was found to have higher abundance of Cytophagia and Nitrospira and a lower abundance of Planctomycetes compared with the soils from the CK treatment. Reduction of Planctomycetes abundance was observed in aerated soils, presumably resulting from the anaerobic nature of these bacteria (Graca et al., 2016). In contrast, Cytophagia and Nitrospira are aerobic bacteria (Parfenova et al., 2013), and their increase suggests that aeration treatment increased the oxygen content in the soil. The results of this study show that rhizosphere aeration through SDI with tanks could promote the activity and reproduction of aerobic bacteria and decrease the growth of anaerobic bacteria.

Ascomycota and Basidiomycota were the most abundant fungal phyla in all of the soil samples, consistent with McGuire et al. (2013) and Schmidt et al. (2013). The abundance of Ascomycota increased significantly with aeration treatment at soil depths of 20 to 30 and 40 to 50 cm, whereas the abundance of Basidiomycota decreased. To the best of our knowledge, no other reports have described the relationship between aeration and Ascomycota or Basidiomycota. Additionally, when comparing phylum abundance in soil samples, enrichment of Ascomycota and depletion of Basidiomycota in aerated soils may be associated with higher oxygen content. Further studies are needed to assess the effects of aeration treatment on these two most common fungal phyla.

Bacteria are the most diverse microbial community in soil. Their community characteristics are sensitive to changes of soil nutrients, pH values, and other external conditions and can reflect changes in soil quality in a timely manner (Vega et al., 2013). The Nitrospira is a kind type of ammonia oxidizing bacteria, and aeration treatment could significantly increase the Nitrospira in the study (Zhao et al., 2017). The results showed that rhizosphere aeration can increase the amount of ammonia-oxidizing bacteria.
in soil and accelerate the transformation of ammonia nitrogen into nitrate nitrogen. The results of key rhizosphere soil bacterial genera and fungal genera showed that aeration treatment could promote the growth of phosphate-solubilizing and potassium-solubilizing microorganisms, increase the availability of soil phosphorus and potassium, and promote the uptake of phosphorus and potassium by plants. Aeration irrigation also promoted the growth of *Fusarium* related to OM decomposition and accelerated the decomposition of OM at a depth of 20 to 30 cm.

Several studies have shown that aeration irrigation can significantly increase the yield and quality of crops, especially in clay and salinized soil (Bhattarai, S. et al., 2008; Shahien et al., 2014). The results of this study showed that aeration irrigation can promote the growth of new parts of grape plants, which is consistent with the previous studies on annual crops (Bhattarai et al., 2004). Carbon isotopic tracing showed that aeration irrigation can be more conducive to carbon allocation and transport to the new branches and fine roots than CK treatment, suggesting that aeration irrigation may have the potential advantage of promoting plant carbon fixation, but further studies are needed in a long period of growth.

Bhattarai et al. (2015) found that aeration irrigation could effectively promote uptake of phosphorus and potassium in plant leaves. The results showed that aeration irrigation promoted the accumulation of nitrogen, phosphorus, and potassium in new leaves and fine roots, and the total content of phosphorus and potassium was significantly higher than that of CK treatment. This may be related to the fact that aeration irrigation can increase the number of P- and K-solubilizing bacteria and promote the decomposition of P and K in soil (Table 1). Previous studies (Lu et al., 2015) have shown that plant C/N ratio was higher under adversity and lower under favorable conditions. In this study, the C/N ratio of new leaves and fine roots was lower than that of CK treatment. We speculate that aerated irrigation can provide a better environment for plant root growth and promote plant growth compared with CK treatment.

### Conclusions

Aeration irrigation through SDI with tanks regulated O\(_2\)/CO\(_2\) content in rhizosphere soil and accelerated air exchange in rhizosphere soil. Aeration through SDI with tanks enhanced the growth of aerobic *Cytophaga* and *Nitrosphira*, inhibited the growth of anaerobic *Planctomycetes*, and increased the abundance of fungi and bacteria at a depth of 40 to 50 cm. It promoted the growth of new leaves, fine roots, and new branches of grape; increased the accumulation of nitrogen, phosphorus, and potassium in new leaves and fine roots; and made photoassimilation distribute advantage of promoting plant carbon fixation.

### Table 1. Effect of aeration irrigation on key rhizosphere soil bacterial genera and fungal genera.

| Soil depth (cm) | Treatment | Pseudomonas | Aspergillus | Bacillus | *Fusarium* |
|----------------|-----------|-------------|-------------|----------|------------|

Values are mean ± se. Data followed by different capital letters in a column indicate a highly significant difference (\(P<0.01\)); different lowercase letters in a column indicate a significant difference (\(P<0.05\)).
to the new branches and fine roots. The results indicated that aeration irrigation through SDI with tanks can promote plant growth. This maybe because aeration irrigation can enhance air exchange and microbial structure in the rhizosphere. This study shows that the aeration irrigation technology has a potential application in greenhouse cultivation, but further study is needed for aerated period, frequency, and intensity.
