BRIEF REPORT

Child Behavior and Sibling Relationship Quality: A Cross-Lagged Analysis

Alison Pike and Bonamy R. Oliver
University of Sussex

Bidirectional associations between sibling relationships and children’s problem behaviors are robust, and links with prosocial behavior have also been reported. Using cross-lagged models, we were able to conservatively test temporal directions of links between positive and negative aspects of sibling relationships and children’s prosocial behavior and conduct problems across a 3-year time span in middle childhood. The Avon Longitudinal Study of Parents and Children (ALSPAC; http://www.bristol.ac.uk/alspac/researchers/data-access/data-dictionary/) is an ongoing population-based study designed to investigate the effects of a wide range of factors on children’s health and development. For the purposes of the current analyses, we included 2,043 ALSPAC families who had just 1 older sibling as well as the target child, with an age gap of no more than 5 years. Mothers reported about the quality of the sibling relationship and both children’s prosocial behavior and conduct problems when the target child was 4 years of age and again when the target child was 7 years old. Confirming our hypothesis, individual child behavior was predictive of sibling relationship quality, and sibling relationship quality was predictive of later child behavior, providing robust evidence of bidirectionality for both prosocial behavior and conduct problems. It would be consistent to expect that an improvement in either sibling relationship quality or individual children’s behavior could have a positive spill over effect. We also found evidence of older sibling dominance in the domain of prosocial behavior and the positive aspects of sibling interaction.

Keywords: Avon Longitudinal Study of Parents and Children (ALSPAC), siblings, prosocial behavior, cross-lagged, conduct problems

Among personal relationships, those between siblings are distinct. First, they are emotionally uninhibited, potentially increasing siblings’ influence on one another (Dunn, 2002). Second, siblings spend a great deal of time together—by middle childhood, the time spent with siblings commonly outstrips that spent with parents (McHale, Whitman, Kim, & Crouter, 2007).

Associations between sibling relationships and children’s conduct problems are well documented (Buist, Dekovic, & Prinzie, 2013), and links with prosocial behavior (e.g., Pike, Coldwell, & Dunn, 2005) and social competence have also been reported (Buist & Vermande, 2014). Such links have been demonstrated longitudinally as well as cross-sectionally, the interpretation of which tends to conceptualize sibling relationship quality as influencing child behavior (e.g., Milevsky, 2011). This interpretation bias has resulted in studies that only test associations in the direction of relationship quality predicting child behavior, most notably longitudinal studies that test associations of sibling relationship quality at an earlier time point, with child behavior at a later time point. For example, Garcia and colleagues (2000) reported significant prediction from sibling conflict at age 5 to aggression at age 6, and Buist and colleagues (2014) demonstrated that sibling conflict was related to higher levels of externalizing problems that then (surprisingly) decreased more swiftly.

There are very few examples of child behavior being used to predict subsequent sibling relationship quality. However, Kramer and Kowal (2005) found that children’s behavior toward a friend in the preschool years predicted the quality of sibling interaction in adolescence. In addition, Stocker, Burwell, and Briggs (2002) showed that sibling conflict in middle childhood predicted symptoms of anxiety, depression, and delinquency 2 years later, and the reverse was not true—child adjustment at the first time point did not predict sibling relationship quality 2 years later.

Using cross-lagged methodology enables the examination of the relative prediction of individual child behavior to sibling relationship quality over time and vice versa while accounting for stability and cross-sectional associations. Testing the temporal pattern of associations between sibling relationship quality and child behavior in this way can inform whether sibling relationships influence child behavior or whether they are merely a reflection of the individual children’s behavioral profiles.
Current Study

For the first time, we used a large, population-based sampling frame to examine longitudinal links between positive and negative aspects of sibling relationships and children’s prosocial behavior and conduct problems. The focus was on sibling pairs in early to middle childhood—the children’s ages ranged from 4 to 12 years. A key feature of the current study was our ability to assess birth order. Would the older siblings maintain their dominance, as is seen in younger children (Dunn, Creps, & Brown, 1996), or is the behavior of younger siblings also important, as would be expected if a more egalitarian relationship has been established by this stage (Buhrmester & Furman, 1990)? We focused on conduct problems because these are the best predictor of diverse mental health problems in adulthood (Kim-Cohen et al., 2003) and prosocial behavior (not merely the absence of antisocial behavior), which predicts long-term education, employment, and criminal outcomes (Jones, Greenberg, & Crowley, 2015). We hypothesized that the temporal flow of influence would be bidirectional.

Method

Sample and Procedure

The Avon Longitudinal Study of Parents and Children (ALSPAC; http://www.bristol.ac.uk/alspac/researchers/data-access/data-dictionary/) is an ongoing population-based study designed to investigate the effects of a wide range of factors on children’s health and development. All women residing in Avon, United Kingdom (UK), with expected dates of delivery between April 1, 1991, and December 31, 1992, were contacted and were eligible for participation (a total of 20,248 eligible pregnancies). Of these, 14,541 (71.8%) women enrolled in ALSPAC during pregnancy in 1990–1992, resulting in 14,062 live-born children and 13,988 children alive at 12 months of age. Compared with the 1991 UK National Census Data, the ALSPAC sample was similar to the population as a whole, except for showing a higher proportion of married or cohabiting mothers; families who were owner–occupiers; and, consistent with the area where the study is based, a smaller proportion of mothers from ethnic minorities (4.1% vs. 7.6%). For more information about the ALSPAC sample, please refer to the works of Boyd et al. (2012); Copeland, Shanahan, Costello, and Angold (2009); and Dunn et al. (2011). Ethical approval for the study was obtained from the ALSPAC Law and Ethics Committee and the local research ethics committees.

Questionnaires were sent to 12,349 mothers and were returned by 9,501 (76.9%) when the target child was 4 years old. When the target child was 7 years old, questionnaires were sent out to 10,662 mothers, of whom 8,505 (79.8%) completed the assessment. In order to control as many extraneous family factors as possible, we elected to include the 2,573 ALSPAC families who had just one older sibling in addition to the target child. We were restricted to the use of older—rather than younger—siblings because of the availability of data. Of these families, we excluded a further 530 families with an age gap of more than 5 years to avoid sibling dynamics that were either disengaged or more akin to a caretaker relationship (Dunn, 2002). The final sample consisted of approximately equal numbers of the four sibling sex constellations in 2,043 families. The age gap between siblings was between 1 and 5 years ($M = 2.37$ years).

Measures

All measures were collected via postal questionnaire when the younger sibling was 4 (Time 1) and 7 (Time 2) years of age. Cronbach’s alphas reported are for the current sibling sample.

Child adjustment. Maternal reports of younger and older sibling conduct problems and prosocial behavior were collected using the Strengths and Difficulties Questionnaire (SDQ; Goodman, 1997). The SDQ is a widely used screening instrument with reliability and validity demonstrated in a large national sample (Goodman, 2001). Mothers are asked to indicate how true different statements of behaviors are about their child within the last 6 months using a 3-point scale ranging from not true (0) through sometimes true (1) to certainly true (2). There are five subscales, two of which were used in the current study: Prosocial Behavior (five items; e.g., considerate of other people’s feelings; $\alpha = .70–.75$) and Conduct Problems (five items; e.g., often fights with other children or bullies them; $\alpha = .49–.58$). The low alphas for the Conduct Problems subscale reflect the small number of items measuring a range of different problems (e.g., often lies or cheats does not have the aggressive element of the fighting or bullying item). These alphas are in line with those of previous reports (e.g., Goodman, 2001; Lewis & Plomin, 2015), and the scale demonstrates good test–retest reliability and clinical validity (Goodman, 1999).

Sibling dyad. The sibling relationship was measured at each time point using the same 16 items that assess a variety of positive and negative aspects of the dyadic relationship. These items were derived from a maternal interview about the sibling relationship (Stocker, Dunn, & Plomin, 1989), which demonstrates good agreement with subsequent child reports about the relationship (Dunn, Slomkowski, Beardsall, & Rende, 1994) and with observations of sibling interaction (Dunn, Stocker, & Plomin, 1990). Mothers were asked to indicate how frequently younger siblings felt or behaved in ways toward the older sibling and the older sibling toward the younger; responses were frequently (2), sometimes (1), or rarely or never (0). Factor analysis indicated two factors that we classify as positivity and negativity in the dyadic relationship. Positivity included eight items (four for younger sibling about older sibling; four for older sibling about younger sibling): likes to be with, wants to play with, has fun with, and misses when away (Cronbach’s $\alpha = .80–.87$). Negativity included eight items (four for each sibling): quarrels with, jealous when mother is with, jealous when father is with, and teases (Cronbach’s $\alpha = .83–.84$).

Statistical Analysis

Before addressing our hypothesis, we conducted tests of measurement invariance using Mplus, Version 6.1.1, running unconstrained and constrained models for prosocial behavior and sibling positivity and for conduct problems and sibling negativity. For the unconstrained models, items for a given scale (e.g., SDQ prosocial behavior, sibling positivity) were considered to be loaded onto latent factors, with loadings free to vary across time point (Time 1 and Time 2) and for younger and older siblings where applicable. For constrained models, loadings were constrained to be equal across both time points and for younger and older siblings. Model fit comparisons from the unconstrained and constrained models were then compared. Measurement invariance was verified for all
measures with no significant change to model fit revealed. Details are available from the first author.

We hypothesized that the temporal flow of influence between sibling relationship quality and child behavior would be bidirectional. To test this hypothesis, cross-lagged models were used. Models were estimated using Mplus, Version 6.1.1, with missing data accounted for using full information maximum likelihood, and were designed to explore the longitudinal relationships between younger and older sibling behavior and dyadic sibling relationships. These models were used to examine the extent to which reciprocal associations were evident between (a) prosocial behavior and positivity in the sibling dyad and (b) conduct problems and negativity in the dyad. Bias-corrected bootstrapped 95% confidence intervals (95% CIs) based on 10,000 samples were used to assess potential differences in the magnitude between similar paths.

Results

Preliminary Analysis

Our first analysis involved creating residual scores of our variables of interest, controlling for the number of boys in the sibling dyad (zero, one, or two), the age of the older sibling at Time 1 (younger sibling age was constant), and maternal education. In combination, these variables accounted for up to 4.0% of the variance for sibling relationship quality and up to 2.3% of the variance for behavior. Standardized, residual scores were used for all further analysis. Correlations for study variables are shown in Table 1. All correlations were in the expected direction—significant at \( p < .001 \) and were small (\( r = .08 \) for older sibling conduct problems with younger sibling prosocial behavior) to large (\( r = .59 \) for dyad negativity across time) in magnitude.

Cross-Lagged Models

Models fit satisfactorily for both prosocial behavior, \( \chi^2(12) = 1,534.34, \ p < .001 \) (root mean square error of approximation [RMSEA] = 0.00; 90% CI [0.00, 0.00]; comparative fit index [CFI] = 1.00; Tucker–Lewis index [TLI] = 1.00), and conduct problems, \( \chi^2(12) = 1,720.33, \ p < .001 \) (RMSEA = 0.00; 90% CI [0.00, 0.00]; CFI = 1.00; TLI = 1.00). The results of these cross-lagged models are shown in Figures 1 and 2.

**Prosocial behavior and sibling dyad positivity.** Within-time associations between younger and older sibling prosocial behavior and sibling dyad positivity are represented by double-headed arrows in Figure 1. Moderate positive associations were evident at Time 1, indicating links between prosocial behavior of younger and older siblings, as well as with positivity in the sibling relationship. According to 95% CIs, associations between positivity and younger and older sibling prosocial behavior were significantly smaller in magnitude at Time 2 than at Time 1, although they were still significant and in the expected direction. Autoregressive pathways in Figure 1 (that is, relationships within the domain across Time 1 and Time 2) suggested considerable stability in prosocial behavior over the 3 years for both younger and older siblings and for positivity in the sibling dyad. Of primary focus are the longitudinal cross-construct connections given by the cross-lagged paths, which indicate the extent to which younger and older siblings’ prosocial behavior and the positivity in the sibling dyad influence one another over time while accounting for within-construct stability. These cross-lagged path coefficients indicated some bidirectionality between siblings’ prosocial behavior and positivity in the sibling dyad—that is, positivity in the sibling dyad at Time 1 was associated with both younger and older sibling prosocial behavior at Time 2, and, similarly, older sibling prosocial behavior at Time 1 was significantly associated with both younger sibling prosocial behavior and sibling dyad positivity at Time 2, even accounting for these constructs at Time 1. Strikingly, younger sibling prosocial behavior at Time 1 did not relate to either older sibling prosocial behavior or positivity in the sibling dyad at Time 2: 95% CIs indicated that these pathways differed significantly from the equivalent older sibling pathways.

**Conduct problems and sibling dyad negativity.** Turning to the results for conduct problems and dyad negativity (see Figure 2), bidirectionality is again seen between child behavior and sibling relationships. For example, within-time associations show a very similar pattern to those for dyad positivity and prosocial behavior. Furthermore, the cross-lagged paths from both older sibling conduct problems and dyad negativity at Time 1 to all three outcomes at Time 2 are also very similar to those seen for prosocial behavior and sibling dyad positivity. However, cross-lagged paths from younger sibling conduct problems show a different pattern from those seen for prosocial behavior. Notably, for conduct problems and sibling dyad negativity, 95% CIs indicate that associations do not differ significantly for younger and older siblings.

Discussion

Using a large, population-based sample of sibling pairs in middle childhood, we replicated previously demonstrated moderate associations between sibling relationship quality and both prosocial behavior and conduct problems. Some evidence of specificity was revealed, in that sibling relationship positivity was more highly correlated with prosocial behavior, whereas negativity was
siblings are still spending large amounts of time with one another were age 4 and the older siblings were as old as 9. At this time, associations at the first time point were more substantial than at the second time point. At the first time point, the younger siblings demonstrate the bidirectional nature of the associations. Although there were strong bidirectional associations, these individual characteristics clearly influence the sibling interactions are not simply a reflection of each child’s behaviors, exhibited across time and context (Pike et al., 2005), and skills such as sharing, cooperation, and empathy—prosocial behaviors exhibited together in a friendly and helpful manner may develop another. Specifically, those brothers and sisters who spend time playing together in a friendly and helpful manner may develop skills such as sharing, cooperation, and empathy—prosocial behaviors exhibited across time and context (Pike et al., 2005), and this may spill over into other social arenas. It is equally true, however, that children who enjoy prosocial interactions with peers may transfer these behaviors to the family environment; past research has shown that children can become nicer siblings “with a little help from their friends” (Kramer & Gottman, 1992, p. 685).

In the case of conduct problems, we confirm that sibling conflict is not harmless; children experiencing high levels of sibling negativity are at much greater risk of behavior problems (Buist et al., 2013). Moreover, our longitudinal findings support the idea that escalating cycles of sibling conflict may effectively “teach” children to behave in antisocial ways (Patterson, 1984). However, predictions from both children’s conduct problems at the first time point to sibling relationship quality at the second time point demonstrate the bidirectional nature of the associations. Although sibling interactions are not simply a reflection of each child’s behaviors, these individual characteristics clearly influence the dyadic relationship.

It was also notable that for both models, the cross-sectional associations at the first time point were more substantial than at the second time point. At the first time point, the younger siblings were age 4 and the older siblings were as old as 9. At this time, siblings are still spending large amounts of time with one another (Dunn, 2002), such that there is plenty of opportunity for mutual influence, and much of the individual children’s behavior ratings will be based on the child’s actions while in the company of the sibling. Three years later, the younger siblings will be well established in school, and time spent with siblings will have declined as time spent with peers increases (Dunn, 2002); we propose that this shift in everyday activities explains the waning of associations over time.

**Older Sibling Dominance**

For prosocial behavior, by the second time point, cross-sectional associations indicate that older sibling behavior is more strongly reflected in sibling positivity than is younger sibling behavior. In addition, older sibling prosocial behavior at Time 1 predicted sibling dyad positivity and younger sibling prosocial behavior at Time 2; younger sibling prosocial behavior had no such influence. Although a similar pattern of findings emerged for conduct problems, differences between older and younger sibling paths were not significantly different in this case.

Overall, we suggest that these results demonstrate that the older siblings within these dyads were more dominant; thus, their own behaviors, and particularly their prosocial proclivities, are reflected in the quality of the sibling relationship to a greater degree than the behaviors of the younger children. This suggestion of older sibling dominance is foreshadowed by research findings employing cross-lagged models of analyses indicating that younger siblings are more influenced by their older siblings’ behavior and adjustment than vice versa (e.g., Hetherington, Henderson, & Reiss, 1999). This influential role of the older sibling begins at the birth of the younger child (see Dunn & Kendrick, 1982); older siblings’ behavior toward the newborn predicts the younger child’s behavior within the sibling relationship years later. While evidence does indicate that sibling relationships become more egalitarian over the course of development (see Dunn, 2002), the current findings suggest that the children in our sample (ages 4–12 years) had not yet reached this stage.
Limitations and Future Directions

Theoretically, the current study is consistent with a family systems perspective, as children within families are not inter-changeable. In addition, the use of cross-sectional analysis is particularly useful in disentangling complex patterns of family influence. However, in order to reduce heterogeneity, we focused on the most typical sibling family type—those families with only two children—but we acknowledge that these findings may not generalize to families with more than two children. Other limitations include the exclusive use of maternal reports, the low internal reliability of the Conduct Problems subscale, and the lack of ethnic diversity. Low internal reliability of the Conduct Problems subscale and lack of ethnic diversity are both factors that would limit reliable variance, thereby serving to depress associations. Sole use of maternal reports, however, may have the effect of inflating the size of associations. Future studies should address these limitations and incorporate additional aspects of the family system. Finally, it is worth noting that these data are now 20 years old. It remains to be seen whether these findings will hold true in the advent of multiple changes, including media and technology.

Implications

Evidence for bidirectionality is good news for clinical applications. It would be consistent to expect that an improvement in either sibling relationship quality or individual children’s behavior could have a positive spill over effect. We also suggest that it may be especially prudent for parents and/or practitioners to focus attention on older siblings’ behavior, particularly on bolstering positive behaviors, because these may be likely to cascade downstream to both younger sibling behavior and the quality of sibling interaction.

Members of Underrepresented Groups: Reviewers for Journal Manuscripts Wanted

If you are interested in reviewing manuscripts for APA journals, the APA Publications and Communications Board would like to invite your participation. Manuscript reviewers are vital to the publications process. As a reviewer, you would gain valuable experience in publishing. The P&C Board is particularly interested in encouraging members of underrepresented groups to participate more in this process.

If you are interested in reviewing manuscripts, please write APA Journals at Reviewers@apa.org. Please note the following important points:

- To be selected as a reviewer, you must have published articles in peer-reviewed journals. The experience of publishing provides a reviewer with the basis for preparing a thorough, objective review.

- To be selected, it is critical to be a regular reader of the five to six empirical journals that are most central to the area or journal for which you would like to review. Current knowledge of recently published research provides a reviewer with the knowledge base to evaluate a new submission within the context of existing research.

- To select the appropriate reviewers for each manuscript, the editor needs detailed information. Please include with your letter your vita. In the letter, please identify which APA journal(s) you are interested in, and describe your area of expertise. Be as specific as possible. For example, “social psychology” is not sufficient—you would need to specify “social cognition” or “attitude change” as well.

- Reviewing a manuscript takes time (1–4 hours per manuscript reviewed). If you are selected to review a manuscript, be prepared to invest the necessary time to evaluate the manuscript thoroughly.

APA now has an online video course that provides guidance in reviewing manuscripts. To learn more about the course and to access the video, visit http://www.apa.org/pubs/authors/review-manuscript-ce-video.aspx.
