ABSTRACT

We study four young pulsar wind nebulae (PWNe) detected in TeV γ-rays, G21.5−0.9, G54.1+0.3, Kes 75, and G0.9+0.1, using the spectral evolution model developed and applied to the Crab Nebula in our previous work. We model the evolution of the magnetic field and the particle distribution function inside a uniformly expanding PWN considering a time-dependent injection from the pulsar and radiative and adiabatic losses. Considering uncertainties in the interstellar radiation field (ISRF) and their distance, we study two cases for each PWN. Because TeV PWNe have a large TeV γ-ray to X-ray flux ratio, the magnetic energy of the PWNe accounts for only a small fraction of the total energy injected (typically a few \times 10^{-3}). The γ-ray emission is dominated by inverse Compton scattering off the infrared photons of the ISRF. A broken power-law distribution function for the injected particles reproduces the observed spectrum well, except for G0.9+0.1. For G0.9+0.1, we do not need a low-energy counterpart because adiabatic losses alone are enough to reproduce the radio observations. High-energy power-law indices at injection are similar (2.5–2.6), while low-energy power-law indices range from 1.0 to 1.6. The lower limit of the particle injection rate indicates that the pair multiplicity is larger than 10^4. The corresponding upper limit of the bulk Lorentz factor of the pulsar winds is close to the break energy of the broken power-law injection, except for Kes 75. The initial rotational energy and the magnetic energy of the pulsars seem anticorrelated, although the statistics are poor.

Key words: ISM: individual objects (G21.5−0.9, G54.1+0.3, Kes 75, G0.9+0.1) – pulsars: general – radiation mechanisms: non-thermal

1. INTRODUCTION

A pulsar wind nebula (PWN) is created by the interaction of the pulsar wind with the surrounding supernova (SN) ejecta (Rees & Gunn 1974; Kennel & Coroniti 1984). The PWN is a shocked pulsar wind composed of a relativistic non-thermal electron–positron plasma and magnetic fields. As a result, a PWN shines from radio through TeV γ-rays via synchrotron radiation and inverse Compton scattering. The observed spectrum of the PWN gives us important information on the pair production multiplicity \( \kappa \) of the central pulsar (de Jager 2007), the magnetization parameter \( \sigma \) in the pulsar wind immediately upstream of the termination shock (Kennel & Coroniti 1984), and the particle acceleration process at the pulsar wind termination shock (e.g., Fang & Zhang 2010). Note that the radiation spectrum depends on time through the evolution of the energy injection, the expansion of the PWN, and radiative and adiabatic losses (e.g., Tanaka & Takahara 2010; Gelfand et al. 2009; Bucciantini et al. 2011).

Through the recent development of γ-ray observations, many PWNe have been discovered in γ-rays and their detailed structures have also been found in other wavelengths (e.g., HESS J1640-465 studied by Aharonian et al. 2006; Lemiere et al. 2009). Although the observed PWNe show common characteristics, such as a flat radio spectrum and X-ray spectral steepening with distance from the pulsar (cf., Gaensler & Slane 2006), they also differ. We discuss the individual differences of PWNe in this paper. These differences include the age and the spin-down power of the central pulsar, the observed size of the PWN, and the TeV γ-ray to X-ray flux ratio. Here we study these characteristics because they constrain the physical condition of the pulsar magnetosphere and the pulsar wind.

We built a spectral evolution model of PWNe in our previous work (Tanaka & Takahara 2010). The application of this model to the Crab Nebula reproduces the current observed spectrum and the radio flux evolution well. In this paper, we apply this model to four young PWNe detected in TeV γ-rays: G21.5−0.9, G54.1+0.3, Kes 75, and G0.9+0.1. We choose these PWNe according to three criteria. (1) They reveal observed non-thermal spectra at least in radio, X-rays, and TeV γ-rays. (2) They have a central pulsar with a known period and derivative. (3) They have an almost spherical shape with a known angular extent, i.e., they are young enough not to reveal signatures of interaction with a supernova remnant (SNR) reverse shock. For application to PWNe other than the Crab Nebula, we include the interstellar radiation field (ISRF) in infrared and optical bands as the target photons of the inverse Compton scattering.

We assume a constant expansion velocity of the PWN. This assumption is appropriate for young PWNe. Gelfand et al. (2009) considered the dynamical evolution of a PWN inside an SNR. Their model of PWN expansion gives a more realistic dynamical evolution than the constant expansion velocity and also applies to old PWNe. However, their expansion model includes many unknown parameters to determine the dynamical evolution including the energy of the SN explosion, the mass of the SN ejecta, and the density of the surrounding interstellar medium. We factor these uncertain quantities into one parameter: the constant expansion velocity. Note that a simple estimate of the radius of the PWN in the early phase of its evolution, \( R_{\text{PWN}} \propto t^{6/5} \) (e.g., van der Swaluw et al. 2001), is close to an expansion at constant velocity.

In Section 2, we describe our model and slightly improve it for application to young TeV PWNe other than the Crab Nebula. In Sections 3–6, we apply the model to G21.5−0.9, G54.1+0.3, Kes 75, and G0.9+0.1 and discuss their individual characteristics. A comparative discussion about the young TeV PWNe we studied, including the Crab Nebula, and the conclusions are given in Section 7.
2. THE MODEL

Here we give a brief description of our spectral evolution model of PWNe (Tanaka & Takahara 2010). For application to young TeV PWNe other than the Crab Nebula, we improve the target photon fields for inverse Compton scattering. We include the ISRF in infrared and optical bands, which were ignored in our previous work. Lastly, we describe the fitting procedure.

2.1. Basic Ingredients of Our Model

We use a one-zone model of PWNe. A PWN is a uniform sphere expanding at a constant velocity $v_{PWN}$, i.e., the radius of a PWN is given by $R_{PWN}(t) = t v_{PWN}$. The contents of the PWN are the magnetic field and the relativistic non-thermal electron–positron plasma which are injected from the central pulsar. The magnetic energy injection $\dot{E}_{\text{mag}}(t) = \eta L(t)$ and the particle energy injection $\dot{E}_{\text{par}}(t) = (1 - \eta) L(t)$ are characterized by the fraction parameter $\eta$ ($0 \leq \eta \leq 1$) and the spin-down power $L(t)$. The evolution of the spin-down power $L(t)$ is given by

$$L(t) = L_0 \left(1 + \frac{t}{t_0} \right)^{-\frac{\eta}{1 - \eta}}, \quad (1)$$

where $L_0$ is the initial spin-down power and $t_0$ is the spin-down time. For $t > t_0$, the total energy injected into the PWN up to time $t$ ($E_{\text{tot}}(t) = \int_0^t L(t') dt'$) approximately corresponds to the initial rotational energy of the central pulsar $L_0 t_0 = I \Omega_0^2 / (n - 1)$, where $\Omega_0 = 2 \pi / P_0$ is the initial angular velocity. For $t < t_0$, $E_{\text{tot}}$ is smaller than $L_0 t_0$. Assuming that the moment of inertia of the pulsar is $10^{45} \text{g cm}^2$, we need four quantities, the current pulsar period $P$, a time derivative $P$, braking index $n$, and the age of pulsar $t_{\text{age}}$, to fix the evolution of the spin-down power. Note that three timescales appear in the spin-down evolution of the pulsar: the age of the pulsar $t_0$, the spin-down time $t_0$, and the characteristic age $t_c$. They are related to each other through the simple relation

$$t_c = \frac{n - 1}{2} (t_0 + t_{\text{age}}). \quad (2)$$

The customarily used braking index $n = 3$ gives $t_c = t_0 + t_{\text{age}}$.

We assume that the distribution of the particles in the PWN is isotropic, and thus the evolution of the particle distribution $N(\gamma, t)$ is given by the continuity equation in energy space,

$$\frac{\partial}{\partial t} N(\gamma, t) + \frac{\partial}{\partial \gamma} (\dot{\gamma}(\gamma, t)N(\gamma, t)) = Q_{\text{inj}}(\gamma, t). \quad (3)$$

We assume that the particle injection $Q_{\text{inj}}(\gamma, t)$ follows the broken power-law distribution

$$Q_{\text{inj}}(\gamma, t) = \begin{cases} Q_0(\gamma / \gamma_b)^{-p_1} & \text{for } \gamma_{\text{min}} \leq \gamma \leq \gamma_b, \\ Q_0(\gamma / \gamma_b)^{-p_2} & \text{for } \gamma_b \leq \gamma \leq \gamma_{\text{max}}, \end{cases} \quad (4)$$

where $\gamma$ is the Lorentz factor of the relativistic electrons and positrons. We introduce the parameters of the injection spectrum, $\gamma_{\text{min}}, \gamma_b, \gamma_{\text{max}}, p_1 < 2$, and $p_2 > 2$, which are the minimum, break, and maximum Lorentz factors and the power-law indices at the low- and high-energy ranges of the injection spectra, respectively. We require that the normalization $Q_0(t)$ satisfies $(1 - \eta) L(t) = \int_{\gamma_{\text{min}}}^{\gamma_{\text{max}}} Q_{\text{inj}}(\gamma, t) \gamma m_e c^2 d\gamma$, where $m_e$ and $c$ are the mass of an electron (or positron) and the speed of light, respectively. We consider the cooling effects of the relativistic particles $\dot{\gamma}(\gamma, t)$ including the synchrotron radiation $\gamma_{\text{syn}}(\gamma, t)$, the inverse Compton scattering off the ISRF $\gamma_{\text{IC}}(\gamma, t)$, and the adiabatic expansion $\gamma_{\text{ad}}(\gamma, t)$. The detailed description of the ISRF will be discussed in Section 2.2. The cooling time of the particles $\tau_{\text{cool}}(\gamma, t) = \gamma / |\dot{\gamma}(\gamma, t)|$ is an important timescale in addition to $t_{\text{age}}$ and $t_0$, and these three timescales characterize the evolution of the particle distribution.

For the magnetic field evolution, we assume the following form of the magnetic field energy conservation:

$$\frac{4\pi}{3} (R_{PWN}(t))^3 \left(\frac{B(t)}{8\pi}\right)^2 \int_0^t \eta L(t') dt' = \eta E_{\text{tot}}(t). \quad (5)$$

The magnetic field approximately evolves as $B(t) \propto t^{-1}$ for $t < t_0$ and $B(t) \propto t^{-1.3}$ for $t > t_0$. Note that some justifications of this magnetic field evolution model are discussed in a previous paper (see Section 2.2 of Tanaka & Takahara 2010).

For the calculation of the radiation spectrum, we assume that the radiation is isotropic. The radiation processes we consider are synchrotron radiation and inverse Compton scattering off the synchrotron radiation (SSC) and the ISRF including the cosmic microwave background (IC/CMB) radiation, infrared photons from dust grains (IC/IR), and optical photons from starlight (IC/OPT).

Lastly, we mention the evolution of the synchrotron cooling break frequency for convenience in the later discussion. Assuming that the inverse Compton cooling is ineffective in most of the evolutionary phase (e.g., Figure 4 of Tanaka & Takahara 2010), we divide the particle distribution into two populations; one corresponds to the high-energy particles which lose energy by synchrotron cooling and the other is the low-energy particles which lose energy by adiabatic cooling. The critical energy $\gamma_c(t)$ is defined by equating the synchrotron cooling time $\tau_{\text{syn}}(\gamma, t)$ with the adiabatic cooling time $\tau_{\text{ad}}(\gamma, t) = t$, which is

$$\gamma_c(t) = \frac{6\pi m_e c}{\sigma_T B^2(t)} \sim 2.45 \times 10^8 \left(\frac{t}{1 \text{ kyr}}\right)^{1/4} \left(\frac{B(t)}{10 \mu G}\right)^{-2}. \quad (6)$$

For $\gamma > \gamma_c(t)$, the synchrotron cooling dominates over the adiabatic cooling and vice versa for $\gamma < \gamma_c(t)$. The characteristic frequency of synchrotron radiation $\nu_{\text{syn}}$ is a function of the particle energy and the magnetic field. Because of the rapid decrease of the magnetic field strength, the synchrotron cooling break frequency $\nu_c(t) \equiv \nu_{\text{syn}}(\gamma_c(t), B(t))$ increases with time, which is

$$\nu_c(t) \sim 1.22 \times 10^{17} \text{ Hz} \left(\frac{\gamma_c(t)}{10^5}\right)^2 \left(\frac{B(t)}{10 \mu G}\right)^{-2} \begin{cases} t & \text{for } t < t_0, \\ t^{2.5} & \text{for } t > t_0. \end{cases} \quad (7)$$

2.2. Galactic Interstellar Radiation Field as the Target of Inverse Compton Scattering

We use the ISRF model described by Porter et al. (2006) as a reference. Their model depends on the distance from the Galactic center $r$ and the height from the Galactic plane $z$. Although the contribution of localized dust and stars to the ISRF changes the actual ISRF around the objects, we ignore the possibility of local effects, except for model 2 of G54.1+0.3.

We assume that the ISRF has three components. The CMB is a blackbody radiation with a temperature of $T_{\text{CMB}} = 2.7$ K. The spectra in the infrared and optical bands are modified blackbodies characterized by a temperature and an energy density
of \((T_R, U_{\text{IR}})\) and \((T_{\text{OPT}}, U_{\text{OPT}})\), respectively. Because the temperature dependence of the IC/IR \((T_R \sim 30–50\; \text{K})\) and the IC/OPT \((T_{\text{OPT}} \sim 3500–4000\; \text{K})\) is weak, we fix \(T_R = 40\; \text{K}\) (mildly Klein–Nishina regime), and \(T_{\text{OPT}} = 4000\; \text{K}\) (mostly Klein–Nishina regime) for all objects. On the other hand, the IC/IR and the IC/OPT luminosities strongly depend on the energy densities \(U_{\text{IR}}\) and \(U_{\text{OPT}}\) which vary with galactic locations. From the distance to each PWN and its galactic coordinates, we can roughly estimate \((r, z)\) for each object. Adopted values for each object are listed in Table 1.

### 2.3. Fitting Procedure

Here we summarize the model parameters and describe the fitting procedure. We adopt the distance to the object \(d\), the angular extent of the object, and the central pulsar parameters \(P, \dot{P}\), and \(n\) from observations. Once the distance to the object is fixed, we can determine the radius of the object \(R_{\text{PWN}}\) and the energy densities of the ISRF \(U_{\text{IR}}\) and \(U_{\text{OPT}}\).

Fitting parameters are the age \(t_{\text{age}}\) (assuming that the age of the central pulsar is the same as that of the PWN), the fraction parameter \(\eta\), and the parameters of the injection spectrum in Equation (4), \(\gamma_{\text{max}}, \gamma_{\text{min}}, \dot{p}_1\), and \(P_2\). In our spectral evolution model, the age \(t_{\text{age}}\) and the fraction parameter \(\eta\) of PWNe are primarily determined by the absolute power of the synchrotron radiation and the power ratio of the inverse Compton scattering to the synchrotron radiation (see Section 3.3 of Tanaka & Takahara 2010). The parameters \(\gamma_{\text{min}}\) and \(\gamma_{\text{max}}\) are relatively unconstrained. We obtain only the upper limit of \(\gamma_{\text{min}}\) from the lowest frequency in radio observations. We choose a lower limit of \(\gamma_{\text{max}}\) so that \(\nu_{\text{syn}}(\gamma_{\text{max}}, B)\) becomes an order of magnitude larger than the observed highest frequency in X-rays since no clear spectral rollover has been observed for the four PWNe.

The fitted parameters which reproduce the multi-wavelength observations are almost uniquely determined except for \(\gamma_{\text{min}}\) and \(\gamma_{\text{max}}\), if we fix the distance to the PWNe and the energy densities of the ISRF. To understand the effects of uncertainties in the observed flux, the measured distance, and the ISRF model on our calculations, we study two different models for each PWN in Sections 3–6.

The adopted and fitted parameters give the values of the expansion velocity \(v_{\text{PWN}}\), the current magnetic field strength of the PWNe \(B_{\text{now}}\), and the parameters of the central pulsars \(t_0\) and \(L_0\). The adopted, fitted, and derived values for each model are listed in Table 1.

### 3. G21.5–0.9

G21.5–0.9 is a composite SNR and its PWN is observed in radio (Salter et al. 1989; Bock et al. 2001), infrared (Gallant & Tuffs 1998), X-rays (Tsujimoto et al. 2011; De Rosa et al. 2009), and TeV \(\gamma\)-rays (Djannati-Ataï et al. 2007b). In X-rays, G21.5–0.9 consists of an outer halo \(\sim 150°\) in radius, which is the SNR component, and a PWN \(\sim 40°\) in radius (Matheson & Safi-Harb 2005, 2010; Bocchino et al. 2005). In radio, the outer halo is not observed and the size of the PWN is comparable to that in the X-rays (Bock et al. 2001; Bietenholz & Bartel 2008; Bietenholz et al. 2011). Infrared observations of PWNe

**Notes.**

$^a$ Results are taken from Tanaka & Takahara (2010).

$^b$ All the adopted parameters are the same as model 1 of G21.5–0.9, but ignoring the observation in infrared.

$^c$ Assumed $U_{\text{IR}}$ is different with model 1 of G54.1+0.3.

$^d$ Assumed distances to the objects are different with model 1 of Kes 75 and G0.9+0.1, respectively.

...
are difficult and G21.5−0.9 is one of the few PWNe whose non-thermal infrared spectrum is observed (Gallant & Tuffs 1998). The Fermi Large Area Telescope (LAT) puts an upper limit on the flux of the PWNe component in GeV γ-rays (Ackermann et al. 2011). The central pulsar of G21.5−0.9 (PSR J1833-1034) is observed in radio and GeV γ-rays with a period $P = 6.19 \times 10^{-2}$ s, a time derivative $\dot{P} = 2.02 \times 10^{-13}$ s$^{-1}$, and an unknown braking index (we assume $n = 3$; Camilo et al. 2006; Abdo et al. 2010). The characteristic age $\tau_c$ of the central pulsar is 4.9 kyr, but Bietenholz & Bartel (2008) suggested $t_{\text{age}} \sim 900$ yr from the observation of the expansion rate of the PWN. On the other hand, Wang et al. (1986) suggested that G21.5−0.9 might be the historical supernova of 48 BC, i.e., $t_{\text{age}} \sim 2$ kyr. We assume that the distance to G21.5−0.9 is 4.8 kpc (Tian & Leahy 2008) and then we approximate the G21.5−0.9 PWN as a sphere of radius 1.0 pc at $(r, z) \sim (4$ kpc, 80 pc). Lasty, we obtain $(U_{\text{IR}}, U_{\text{OPT}}) = (1.0$ eV cm$^{-3}, 2.0$ eV cm$^{-3}$) as the energy density of the ISRF. Considering that the observed infrared spectrum of G21.5−0.9 is uncertain, we investigate two cases: with (model 1) and without (model 2) infrared fitting.

3.1. Model 1

Figure 1 shows the model spectrum of G21.5−0.9 with observational data including the infrared observation. We fit the data with the parameters $\eta = 1.5 \times 10^{-2}$, $t_{\text{age}} = 1.0$ kyr, $\gamma_{\text{max}} = 2.0 \times 10^5$, $\gamma_\beta = 1.2 \times 10^5$, $\gamma_{\text{min}} = 3.0 \times 10^3$, $P_1 = 1.0$, and $p_2 = 2.55$. The fitted fraction parameter is three times larger than the Crab Nebula, but still much smaller than unity. The fitted age $t_{\text{age}} = 1.0$ kyr deviates from the characteristic age of the central pulsar $\tau_c = 4.9$ kyr. Because the ratio of the fitted age to the characteristic age of the pulsar is described as $t_{\text{age}}/\tau_c = 2/(n - 1)[1 - (P_0/P)^{\eta-1}]$, the current pulsar period is almost the same as the initial one ($P_0/P \sim 0.9$). The derived expansion velocity $v_{\text{exp}} = 980$ km s$^{-1}$ and the fitted age are consistent with the observed expansion rate (Bietenholz & Bartel 2008). From the fitted age, we obtain a spin-down time $t_0 = 3.9$ kyr and an initial rotational energy of the pulsar $L_0 t_0 = 6.5 \times 10^{48}$ erg. The current total energy injected into the PWN $E_{\text{tot}}(1 \text{ kyr}) = 1.3 \times 10^{48}$ erg is significantly below $L_0 t_0$, since $t_0 > t_{\text{age}}$. The current magnetic field strength of G21.5−0.9 turns out to be $B_{\text{now}} = 64 \mu$G. We choose $\gamma_{\text{min}}$ and $\gamma_{\text{max}}$ by taking $v_{\text{syn}}(\gamma_{\text{min}}, B_{\text{now}}) \sim 10^8$ Hz and $v_{\text{syn}}(\gamma_{\text{max}}, B_{\text{now}}) \sim 3 \times 10^{19}$ Hz, respectively.

There are two breaks in the calculated synchrotron spectrum in Figure 1. One is the synchrotron cooling break frequency $\nu_c \sim 3 \times 10^{15}$ Hz, which is determined from Equation (7), the other is the break in the particle injection $v_{\text{syn}}(\gamma_b, B_{\text{now}}) \sim 8 \times 10^{11}$ Hz, which is much smaller than $\nu_c$. Since $2 < p_2 < 3$, the synchrotron spectrum in Figure 1 peaks at around $\nu_c$. Focusing on the calculated TeV spectrum in Figure 1, the IC/IR is found to dominate and the SSC contribution is negligible. Although the energy density of the ISRF in the optical band is twice as large as that in the infrared band, the Klein–Nishina effect significantly reduces the IC/OPT. The calculated flux of the GeV γ-ray is almost an order of magnitude below the upper limit of the PWN component given by Ackermann et al. (2011). In hard X-rays, the observed spectrum in $5 \times 10^{18}$ to $2 \times 10^{19}$ Hz is well reproduced, while the pulsar emission appears to dominate above $2 \times 10^{19}$ Hz (De Rosa et al. 2009). The observed spectrum in soft X-rays ($<3 \times 10^{18}$ Hz) and the observed sharp break around $3 \times 10^{18}$ Hz are difficult to reproduce in our model. The observed soft X-ray spectrum is much harder than the calculated spectrum and such a hard spectrum does not smoothly connect to the observed infrared spectrum. We will discuss these discrepancies between the calculated and observed spectra in soft X-rays in Section 3.3.

Figure 2 shows the evolution of the emission spectrum (left panel) and that of the particle distribution (right panel) of G21.5−0.9 with the use of the same parameters as in Figure 1. While the synchrotron flux decreases with time, the inverse Compton flux increases. This feature is due to the decrease of the magnetic field strength with time and to the increase of the particle number as seen in the right panel. Because the energy injection from the pulsar will continue until time $t \sim t_0 = 3.9$ kyr, the particles in the PWN increase (see the discussion in Section 3.2 of Tanaka & Takahara 2010 for details). In the left panel, we can see the evolution of the synchrotron cooling break frequency $\nu_c(t)$ (from $\sim 7 \times 10^{14}$ Hz at 300 yr to $\sim 10^{15}$ Hz at 10 kyr) as is predicted by Equation (7).

3.2. Model 2

The calculated spectrum in model 1 does not reproduce the observed spectrum in infrared and soft X-rays at the same time. Considering the uncertainties in the infrared observations, we try to fit the observed spectrum ignoring the infrared band. Figure 3 shows the model spectrum of G21.5−0.9 without infrared fitting. All the fitted parameters are similar to model 1 (see Table 1), but a slightly smaller value of the fraction parameter $\eta = 8 \times 10^{-3}$ $(B_{\text{now}} = 47 \mu$G) is allowed. Consequently, the synchrotron flux in infrared is smaller than model 1 and the synchrotron cooling break frequency $\nu_c \sim 7 \times 10^{15}$ Hz is a little larger than model 1. The observed spectrum in soft X-rays and the observed sharp break at around $3 \times 10^{18}$ Hz are not well reproduced, even if we ignore infrared observations. The hard X-ray observation ($5 \times 10^{18}$–$2 \times 10^{19}$ Hz) is reproduced as well as model 1.

3.3. Discussion of Models

Both models 1 and 2 reproduce the observational data reasonably well. The fraction parameter $\eta$, i.e., the magnetic field strength $B_{\text{now}}$, is the only notable difference between the
models. Future observations in the infrared and optical bands will provide a more accurate spectrum of G21.5−0.9 and could provide a distinction between the models. As for the other parameters, the values of $\gamma_b$ and $p_1$ are smaller than the Crab Nebula in both models. However, the high-energy power-law index at injection $p_2$ is very similar to the Crab Nebula.

We compare our results with the model of de Jager et al. (2009). They solved hydrodynamic equations and calculated the evolution of the magnetic field separately using the induction equation. The evolution of the broadband spectrum is calculated with a one-zone approach with the use of the volume-averaged magnetic field. Their adopted energy density of the ISRF in the infrared band $U_{\text{IR}} = 1.0 \text{ eV cm}^{-3}$ and $t_{\text{age}} = 1 \text{ kyr}$ are the same as ours. They obtain a particle injection distribution with $p_1 = 1.0$, $p_2 = 2.6$, and $\gamma_b \sim 8 \times 10^4$, which are almost the same as ours. Their obtained current magnetic field strength $\sim 24 \mu G$ is smaller than ours, $B_{\text{now}} = 64 \mu G$ and $47 \mu G$ for models 1 and 2, respectively. Their results are basically consistent with ours.

Lastly, we discuss the discrepancy between our model spectra and the observations in soft X-rays. Tsujimoto et al. (2011) show that there is an observed spectral break between the soft and hard X-rays at $\sim 3 \times 10^{18} \text{ Hz}$. One might consider that this spectral break corresponds to the synchrotron cooling break frequency $\nu_c$. With $t_{\text{age}} = 1 \text{ kyr}$, the value of $\nu_c \sim 3 \times 10^{18} \text{ Hz}$ requires the magnetic field strength to be $\sim 6 \mu G$ from Equation (7). However, the current magnetic field of $\sim 6 \mu G$ seems unlikely because the observed $\gamma$-ray to X-ray flux ratio would demand the local ISRF energy density around G21.5−0.9 to be much smaller than the contribution from the CMB. Note that it is hard to reproduce the observed sharp spectral break at $\sim 3 \times 10^{18} \text{ Hz}$, even if the magnetic field strength is $\sim 6 \mu G$. This is because the evolution of the magnetic field $B(t)$ and the particle injection $Q_{\text{inj}}(\gamma, t)$ makes the synchrotron cooling break rather smooth. We thus conclude that any one-zone spectral evolution model fails to reproduce the current soft X-ray observation. One possible resolution is a modification of the observed spectrum in soft X-rays with relatively large interstellar extinction toward G21.5−0.9 as discussed by Safi-Harb et al. (2001). Another possibility is the effect of spatial variation of the soft X-ray photon index $\Gamma_X$ as discussed by Slane et al. (2000).

4. G54.1+0.3

G54.1+0.3 is a filled center or possibly a composite SNR and its PWN component is observed in radio (Green 1985; Velusamy et al. 1986; Velusamy & Becker 1988; Lang et al. 2010), X-rays (Lu et al. 2001), and TeV $\gamma$-rays (Acciari et al. 2010). In X-rays, a jet-torus structure is observed similar to that of the Crab Nebula (Lu et al. 2002). The size of the radio PWN $\sim 2.5 \times 2.0$ is comparable with that of X-rays (Lang et al. 2010; Bocchino et al. 2010). Recently, diffuse X-ray emission surrounding the PWN was detected by Bocchino et al. (2010), which is a possible counterpart of the SN ejecta component, while a possible SNR shell is observed in radio (Lang et al. 2010). The region around G54.1+0.3 has been observed in the infrared (Koo et al. 2008; Temim et al. 2010). Although no infrared counterpart of G54.1+0.3 PWN is observed, there are several bright sources around G54.1+0.3. The central pulsar of G54.1+0.3 (PSR J1930+1852) is observed in radio and X-rays with a period $P = 1.36 \times 10^{-1}$ s, a time derivative $\dot{P} = 7.51 \times 10^{-13}$ s s$^{-1}$ ($\tau_c = 2.9$ kyr), and an unknown braking index (Camilo et al. 2002). Therefore, we assume $n = 3$. The actual age of G54.1+0.3 is unknown. We assume a distance to G54.1+0.3 of 6.2 kpc (Leahy et al. 2008) and then we assume that G54.1+0.3

Figure 2. Evolution of the emission spectrum (left panel) and the particle distribution (right panel) of G21.5−0.9 for model 1. The solid line, dashed line, dot-dashed line, and dotted line correspond to 300 yr, 1 kyr, 3 kyr, and 10 kyr from birth, respectively. The thin dotted line in the particle distribution (right panel) is the total injected particles at an age of 10 kyr.

Figure 3. Model spectrum of G21.5−0.9 at $t_{\text{age}} = 1.0$ kyr for model 2, where we ignore the infrared observation (Gallant & Tuffs 1998) in the spectral fitting. Used and obtained parameters are given in Table 1.
PWN has a sphere with radius 1.8 pc at \((r, z)\) \(\sim (7.5\) kpc, 0 pc\). We obtain \((U_{\text{IR}}, U_{\text{OPT}}) = (0.5\) eV cm\(^{-3}\), 0.5 eV cm\(^{-3}\)) for the energy density of the ISRF in model 1. We also investigate in model 2 the probability that the observed infrared sources around G54.1+0.3 significantly contribute to the local ISRF.

### 4.1 Model 1

Figure 4 shows the model spectrum of G54.1+0.3 for model 1 with the observational data. We can reproduce the observed non-thermal spectrum with the parameters \(\eta = 3.0 \times 10^{-4}\), \(t_{\text{age}} = 2.3\) kyr, \(\gamma_{\text{max}} = 1.0 \times 10^9\), \(\gamma_{\text{min}} = 3.0 \times 10^3\), \(\tau_c = 2.0 \times 10^4\), \(p_1 = 1.2\), and \(p_2 = 2.55\). The fraction parameter is 0.06 times the Crab Nebula’s value. The fitted age \(t_{\text{age}} = 2.3\) kyr is comparable to the characteristic age of the central pulsar \(\tau_c = 2.9\) kyr, and the current period is almost twice as large as the initial period. The corresponding expansion velocity \(v_{\text{exp}} = 770\) km s\(^{-1}\) is less than half of that of the Crab Nebula’s 1800 km s\(^{-1}\). We obtain a spin-down time \(\tau_0 = 0.6\) kyr < \(t_{\text{age}}\) and an initial rotational energy \(L_0\tau_0 = 5.4 \times 10^{48}\) erg. The current total energy injected into the PWN \(E_{\text{tot}}(2.3\) kyr) = 4.3 \(\times 10^{48}\) erg is close to the value of \(L_0\tau_0\). The current magnetic field strength of G54.1+0.3 turns out to be \(B_{\text{now}} = 6.7\) \(\mu G\), which is much smaller than that of the Crab Nebula and G21.5–0.9.

The synchrotron cooling break frequency \(\nu_c \sim 5 \times 10^{17}\) Hz is much larger than the characteristic synchrotron frequency corresponding to the break energy \(\nu_{\text{syn}}(\gamma_t, B_{\text{now}}) \sim 7 \times 10^{15}\) Hz. In \(\gamma\)-rays, the ISRF energy density in the infrared band is twice as large as that of the CMB, but the contributions of the IC/CMB and the IC/IR are comparable because the IC/IR is in the mild Klein–Nishina regime. To explain further, the observed X-ray spectrum seems consistent with the model spectrum, while the observed \(\gamma\)-ray spectrum seems softer. Because particles with almost the same energy contribute both to the observed emission in X-rays (SYN) and \(\gamma\)-rays (IC/CMB in the Thomson regime), it is difficult to fit the spectral slopes in both frequency ranges at the same time.

Figure 5 shows the evolution of the emission spectrum (left panel) and the particle distribution (right panel) of G54.1+0.3 using the same parameters as in Figure 4. Both the synchrotron flux and the IC flux decrease with time, but the IC flux decreases more slowly. This is because the decrease of the magnetic field strength is much faster than the particle distribution while the ISRF energy density is constant. This behavior of the particle distribution has already been discussed in Section 3.2 of Tanaka & Takahara (2010). In short, the evolution of the particle number is approximately expressed as \(N(\gamma, t) = Q(\gamma, t) \tau_{\text{cool}}(\gamma, t)(t + \tau_{\text{cool}}(\gamma, t))\) and the injection from the pulsar decreases as \(Q(\gamma, t) \propto t^{-2}\) after the time \(t \sim \tau_0 = 600\) yr. In the synchrotron cooling regime \(\tau_{\text{cool}} = \tau_{\text{syn}} < \tau_{\text{ad}}\), the particle number increases as \(N \propto t\), while in the adiabatic cooling regime \(\tau_{\text{cool}} = \tau_{\text{ad}}\), the particle number decreases as \(N \propto t^{-1}\), where we use \(\tau_{\text{syn}} \propto t^3\) for \(t > \tau_0\). Figure 5 (left) shows that the synchrotron cooling break frequency \(\nu_c(t)\) will continue to increase with time until an age of 3 kyr (Equation (7)). Because \(\gamma_{\text{c}}(10\) kyr) > \(\gamma_{\text{max}}\), the synchrotron spectrum will peak at \(\nu_{\text{syn}}(\gamma_{\text{max}})\), not \(\nu_c\), at an age of 10 kyr.

### 4.2 Model 2

The region around G54.1+0.3 has been observed in the infrared (Koo et al. 2008; Temim et al. 2010) and observations suggest that the ISRF around G54.1+0.3 could be larger than that of the average values of the galaxy adopted in model 1. Figure 6 shows the model spectrum of G54.1+0.3 for model 2 when the energy density of the ISRF in the infrared band has been chosen to be four times larger than that of model 1 \((U_{\text{IR}} = 2.0\) eV cm\(^{-3}\)). All the fitted parameters are similar to model 1, except for the fraction parameter and the fitted age; they are \(\eta = 2.0 \times 10^{-3}\) and \(t_{\text{age}} = 1.7\) kyr, respectively (see Table 1). The fitted fraction parameter is close to the values of the Crab Nebula. The fitted age \(t_{\text{age}} = 1.7\) kyr is similar to the independent estimate of 1.5 kyr from the dynamical interaction with SNR by Chevalier (2005). Because the fitted age \(t_{\text{age}}\) changes from model 1, the derived parameters also change from model 1, \(\nu_{\text{exp}} = 1040\) km s\(^{-1}\), \(\tau_0 = 1.2\) kyr, and \(L_0\tau_0 = 2.6 \times 10^{48}\) erg \((E_{\text{tot}}(1.7\) kyr) = 1.6 \(\times 10^{48}\) erg), respectively. The current magnetic field strength \(B_{\text{now}} = 10\) \(\mu G\) becomes a little larger than that of model 1. We can see the trend that a larger energy density of the ISRF leads to a larger \(\eta\) and \(B_{\text{now}}\) and a smaller value of \(E_{\text{tot}}(t_{\text{age}})\) and \(t_{\text{age}}\). This trend can be understood following a similar discussion made in Section 3.3 of Tanaka & Takahara (2010; see Section 7.1).

### 4.3 Discussion

We favor model 2 because the observed \(\gamma\)-ray spectrum is somewhat better reproduced by model 2, although both models 1 and 2 can reproduce the observational data reasonably well; model 2 has a softer \(\gamma\)-ray spectrum than model 1 although the contribution of the IC/IR is larger than the IC/CMB. Because the difference of the ISRF energy density in the models appears at the frequency where the Klein–Nishina effect works, future observations in higher energy \(\gamma\)-rays (1–100 TeV), such as Cherenkov Telescope Arrays, would provide better information on the correct values of the ISRF. In contrast to \(\eta\) and \(t_{\text{age}}\), the parameters of the particle injection for both models are similar.

The low-energy power-law index at injection \(p_1\) is different from the Crab Nebula and G21.5–0.9, but the high-energy power-law index at injection \(p_2\) is very similar.

The spectral evolution of G54.1+0.3 was also studied by Li et al. (2010). In addition to the pure-lepton model (Figure 2 of Li et al. 2010), they studied a lepton–hadron hybrid model of the broadband spectrum (Figure 3 of Li et al. 2010). In the
pure-lepton model, they obtained the parameters $p_1 = 1.2$ and $y_b = 5 \times 10^5$, which are similar to ours. However, their obtained $p_2 = 2.8$ and adopted $U_{IR} \sim 3.3$ eV cm$^{-3}$ are different from ours in model 2, $p_2 = 2.55$ and $U_{IR} \sim 2.0$ eV cm$^{-3}$, respectively. A difference appears in the X-ray spectrum, which seems softer in their model than ours. The current magnetic field strength in their model $\sim 10 \mu$G is the same as in our model 2. We conclude that their pure-lepton model is almost consistent with model 2 of ours except for the X-ray spectrum.

Li et al. (2010) argued that the lepton–hadron hybrid model ($B \sim 80 \mu$G) is better than the pure-lepton model because the current magnetic field $B \sim 10 \mu$G in the pure-lepton model is much weaker than the observational indication by Lang et al. (2010). Lang et al. (2010) estimated an equipartition magnetic field of 38 $\mu$G from the radio luminosity of PWN and a magnetic field of 80–200 $\mu$G from the lifetime of X-ray-emitting particles. We consider that these estimates by Lang et al. (2010) are not robust. Generally, the magnetic field strength is sub-equipartition for all PWNes we studied, i.e., $\eta \ll 1$, so that $B = 10 \mu$G is just a reasonably expected value for this PWN. Li et al. (2010) also argued that the observed $\gamma$-ray photon index is better fitted by the lepton–hadron hybrid model than the pure-lepton model. However, the calculated $\gamma$-ray spectrum in the pure-lepton model changes with the local ISRF energy density and temperature. We believe that a leptonic model with small magnetic field is consistent with the current observations.

5. KESTEVEN 75

Kes 75 is a composite SNR and its PWN component is observed in radio (Salter et al. 1989; Bock & Gaensler 2005), X-rays (Helfand et al. 2003; McBride et al. 2008), and TeV $\gamma$-rays (Djannati-Ataï et al. 2007a). In X-rays, a jet-torus structure is observed (Ng et al. 2008). This jet-torus structure is surrounded by a diffuse X-ray nebula, which has almost the same extent as that of the radio PWN $\sim 26' \times 20''$ (Helfand et al. 2003). A part of the SNR shell is observed in radio and X-rays (Bock & Gaensler 2005; Helfand et al. 2003). The central pulsar of Kes 75 (PSR J1846-0258) is observed in X-rays, with a period $P = 3.26 \times 10^{-4}$ s, its time derivative $P = 7.08 \times 10^{-12}$ s s$^{-1}$, and braking index $n = 2.65 \pm 0.01$ (Livingstone et al. 2006). Although the characteristic age $\tau_c = 0.7$ kyr of the central pulsar suggests that it is very young, the actual age of the Kes 75 is unknown. PSR J1846-0258 has a large surface dipole magnetic field and a magnetar-like burst was observed in 2006 (Gavriil et al. 2008). No radio counterpart of PSR J1846-0258 is observed, common to most of the magnetar candidates (Archibald et al. 2008). We consider two cases for the distance to Kes 75: 6 kpc (Leahy & Tian 2008) and 10.6 kpc (Su et al. 2009) as models 1 and 2, respectively. We assume that Kes 75 PWN is a sphere of radius 0.29 pc ($r \approx 50$ pc) for model 1, and ($r, z \sim (4$ kpc, 30 pc) or 0.5 pc at ($r, z \sim (5$ kpc, 50 pc) for models 1 and 2, respectively. The energy density of the ISRF is $(U_{IR}, U_{OPT}) = (1.2$ eV cm$^{-3}, 2.0$ eV cm$^{-3}$) for model 1 and $(U_{IR}, U_{OPT}) = (1.0$ eV cm$^{-3}, 2.0$ eV cm$^{-3}$) for model 2, respectively.

5.1. Model 1

Figure 7 shows the model spectrum of Kes 75 when the distance to Kes 75 is assumed to be 6 kpc together with observational data. We fit the data with the parameters $\eta = 5.0 \times 10^{-5}$, $\tau_{age} = 0.7$ kyr, $\gamma_{max} = 2.0 \times 10^3$, $y_b = 2.0 \times 10^6$, $\gamma_{min} = 5.0 \times 10^3$, $p_1 = 1.6$, and $p_2 = 2.5$. The fraction parameter is very small—two orders of magnitude smaller than the Crab Nebula. The fitted age $\tau_{age} = 0.7$ kyr and the expansion velocity $v_{PWN} = 420$ km s$^{-1}$ is rather slow. The pulsar parameters
$t_0 = 0.2 \text{ kyr}$ and $L_0 t_0 = 1.5 \times 10^{48} \text{ erg}$ are also smaller than those of the other PWNe. The small $t_0$ may be related to the large magnetic field of the PSR J1846-0258. The current total energy $E_{\text{tot}}(0.7 \text{ kyr}) = 9.1 \times 10^{47} \text{ erg}$ is roughly half of $L_0 t_0$. The current magnetic field strength of Kes 75 turns out to be $B_{\text{now}} = 20 \mu \text{G}$. Despite $\eta$ being more than an order of magnitude smaller than in the other PWNe, $B_{\text{now}}$ is not so different because the size of the Kes 75 PWN is small, and accordingly, $\nu_{\text{pWN}}$ is small.

Focusing on the detailed spectral features, the observed flux in hard X-rays is not well reproduced and is a few times larger than the model prediction although the characteristic synchrotron hard X-ray observation is difficult to reproduce because the small spin-down time $\tau_0 = 0.2 \text{ kyr}$.

$\gamma_\text{max}$ extends to $\sim 3 \times 10^{20} \text{ Hz}$. The hard X-ray observation is difficult to reproduce because the synchrotron cooling break frequency $\nu_c \sim 2 \times 10^{13} \text{ Hz}$ is located in the soft X-rays (see the discussion in Section 5.3). The $\gamma$-ray emission is IC/IR dominant as in G21.5−0.9 and G54.1+0.3.

Figure 8 shows the evolution of the emission spectrum (left panel) and the particle distribution (right panel) of Kes 75 using the same parameters as in Figure 7. Both the synchrotron flux and the IC flux decrease with time. This feature is similar to

$E_{\text{tot}}(10 \text{ kyr}) = 1.7 \times 10^{40} \text{ erg}$ is also smaller than in model 1. The fitted age $t_{\gamma\text{age}} = 0.88 \text{ kyr}$ is almost the maximum value given by Equation (2). The current magnetic field strength $B_{\text{now}}$ is $24 \mu \text{G}$, similar to model 1 because the adopted ISRF energy density is similar. On the other hand, given the larger $\gamma$-ray luminosity, $E_{\text{tot}} = 1.7 \times 10^{40} \text{ erg}$ is more than two orders of magnitude larger than model 1. The pulsar parameters $t_0 = 3 \text{ yr}$ and $L_0 t_0 = 2.1 \times 10^{39} \text{ erg} \sim E_{\text{tot}}$ are more extreme than model 1.

To better reproduce the observed $\gamma$-ray flux in model 2, $E_{\text{tot}}$ larger than $1.7 \times 10^{30} \text{ erg}$ is required with the adopted ISRF energy density. $E_{\text{tot}} \gg 1.7 \times 10^{30} \text{ erg}$ leads to $t_0 < 3 \text{ yr}$ and $L_0 t_0 > 2.1 \times 10^{30} \text{ erg}$. However, $t_0 = 3 \text{ yr}$ is extremely short.

G54.1+0.3 (Figure 5) because of the small spin-down time $t_0 = 0.2 \text{ kyr}$.

5.2. Model 2

Figure 9 shows the model spectrum of Kes 75 when the distance to Kes 75 is assumed to be 10.6 kpc together with observational data. We calculate the spectrum with the parameters $\eta = 6.0 \times 10^{-6}$, $t_{\gamma\text{age}} = 0.88 \text{ kyr}$, $\gamma_{\text{max}} = 1.0 \times 10^9$, $\nu_0 = 5.0 \times 10^6$, $\nu_{\text{min}} = 5.0 \times 10^5$, $p_1 = 1.4$, and $p_2 = 2.5$, but the calculated $\gamma$-ray flux is a few times smaller than the observed one. The fraction parameter is an order of magnitude smaller than that in model 1. The fitted age $t_{\gamma\text{age}} = 0.88 \text{ kyr}$ is almost the maximum value given by Equation (2). The current magnetic field strength $B_{\text{now}}$ is $24 \mu \text{G}$, similar to model 1 because the adopted ISRF energy density is similar. On the other hand, given the larger $\gamma$-ray luminosity, $E_{\text{tot}} = 1.7 \times 10^{40} \text{ erg}$ is more than two orders of magnitude larger than model 1. The pulsar parameters $t_0 = 3 \text{ yr}$ and $L_0 t_0 = 2.1 \times 10^{39} \text{ erg} \sim E_{\text{tot}}$ are more extreme than model 1.
compared with $t_{age} = 0.88$ kyr and $L_0 t_0 = 2.1 \times 10^{50}$ erg is three times larger than the Crab Pulsar. On the other hand, these extreme $t_0$, $L_0$, and also $\eta$ may be allowed given the unique properties of the central pulsar PSR J1846-0258, and in this case an energy density of the ISRF a few times larger would reproduce the observed $\gamma$-ray flux.

5.3. Discussion

We favor model 1 rather than model 2 when we compare the parameters with the other PWNe, because model 2 of Kes 75 is clearly more extreme than model 1. However, we find Kes 75 peculiar in its results, even for the distance of 6 kpc (model 1). The fitted values of $\eta = 5 \times 10^{-3}$ and $v_{PWN} = 420 \text{ km s}^{-1}$ are significantly smaller than other PWNe we studied so far. The parameters $\eta$ and $v_{PWN}$ become large, if we increase the local ISRF energy density $U_{ISRF}$ in the same manner as in model 2 of G54.1+0.3. However, to obtain a two orders of magnitude larger value of $\eta$ and $v_{PWN} \sim 1000 \text{ km s}^{-1}$, more than an order magnitude larger $U_{ISRF}$ is needed (see Section 7.1 for details) and the age of the pulsar $t_{age}$ becomes around 300 yr, which is as small as the age of SNR Cassiopeia A. Because Kes 75 is the youngest PWN in our study, more precise studies of how a PWN is created inside an SNR may be important besides the magnetar-like properties of its central pulsar PSR J1846-0258. As for the particle injection, the parameters are not unusual except for the slightly larger value of $\eta$ compared with other PWNe. The high-energy power-law index at injection $p_2 = 2.5$ is similar to that of other PWNe.

Bucciantini et al. (2011) studied Kes 75 with their spectral evolution model. There are two main differences between their model and ours. First, while we model the magnetic field evolution assuming energy conservation (Equation (5)), they consider the adiabatic loss of magnetic energy. Second, they consider the dynamical evolution of a PWN inside an SNR. The age of the system is determined from the dynamical properties of the system in their model, while we determine it from the spectral properties. They assume that the age of the system is 650 yr, which is close to our result of 700 yr. The parameters of the particle injection $p_1 = 1.7$ and $\eta = 8 \times 10^{6}$ are almost consistent with our model $p_1 = 1.6$ and $\eta = 2 \times 10^{6}$, but the high-energy power-law index at injection $p_2 = 2.3$ is a little harder than our value $p_2 = 2.5$. The lower value of $p_2$ increases the calculated flux in the hard X-rays, but their fitted spectrum still underpredicts the hard X-ray observation. Their current magnetic field strength $\sim 30 \mu G$ is almost consistent with our model $B_{now} = 20 \mu G$, but the adopted energy density of the ISRF $\sim 24 \text{ eV cm}^{-3}$ is very large. However, because the assumed temperature of the ISRF $T_{ISRF} = 1000 \text{ K}$ is high, the Klein–Nishina effect significantly suppresses the IC/ISRF flux in their model.

The uniqueness of Kes 75 PWN also appears in Bucciantini et al. (2011). For the case of Kes 75, the fraction of the magnetic energy injection $E_{mag}$ of the spin-down power $L(t)$ (corresponding to $\eta$ in our model) is almost two orders of magnitude lower than other young PWNe in both studies. This relative smallness of $\eta$ compared with other young PWNe is likely to be real and is very interesting, although the absolute value of $\eta$ is different between Bucciantini et al. (2011) and the present work. The difference in the absolute value of $\eta$ is most probably due to the difference in the magnetic field evolution model.

Lastly, we discuss the hard X-rays. McBride et al. (2008) argued that the hard X-ray emission detected by INTEGRAL is dominated by emission from the PWN, i.e., it is not from the pulsar. However, it is difficult to reproduce the observed hard X-ray emission with the current magnetic field $B_{now} = 20 \mu G$. If both the observed soft and hard X-ray spectra are fitted by power-law spectra as discussed in McBride et al. (2008), the synchrotron cooling break frequency $\nu_c$ should be above $10^{19}$ Hz ($B_{now} \sim 5 \mu G$ for $t_{age} = 0.7$ kyr) to reproduce the observed soft X-ray photon index $\Gamma_X < 2$. This is difficult to realize for the same reason as for G21.5−0.9 because the observed $\gamma$-ray to X-ray flux ratio constrains the current magnetic field strength. Note that the hard X-ray emission may have a pulsar origin.

6. G0.9+0.1

G0.9+0.1 is a composite supernova remnant and its PWN component is observed in radio (Dubner et al. 2008), X-rays (Gaensler et al. 2001), and TeV $\gamma$-rays (Aharonian et al. 2005). In X-rays, a jet-torus-like structure is observed (Gaensler et al. 2001; Porquet et al. 2003). In radio, G0.9+0.1 consists of a compact PWN with a radius of $\sim 1'$ and an outer SNR shell with a radius of $\sim 4'$ (Dubner et al. 2008). No X-ray counterpart of the outer SNR shell is observed (Porquet et al. 2003). The central pulsar of G0.9+0.1 (PSR J1747-2809) has recently been detected in radio, with a period $P = 5.22 \times 10^{-2}$ s, a time derivative $\dot{P} = 1.56 \times 10^{-13} \text{ s}^{-1}$ ($\tau_c = 5.3$ kyr), and an unknown braking index (Camilo et al. 2009). We assume $n = 3$. The actual age of G0.9+0.1 is unknown. We consider two cases for the distance of G0.9+0.1: 8 kpc (lower limit) and 13 kpc (upper limit) given by Camilo et al. (2009) as models 1 and 2, respectively. The ISRF energy density of model 1 is larger than model 2, especially in optical band. We assume that G0.9+0.1 PWN is a sphere of radius 2.3 pc at $(r, z) \sim (0 \text{ kpc}, 15 \text{ pc})$ or 3.8 pc at $(r, z) \sim (5 \text{ kpc}, 20 \text{ pc})$ for models 1 and 2, respectively. The energy density of the ISRF is $(U_{IR}, U_{OPT}) = (1.6 \text{ eV cm}^{-3}, 15 \text{ eV cm}^{-3})$ for model 1 and $(U_{IR}, U_{OPT}) = (1.2 \text{ eV cm}^{-3}, 2.0 \text{ eV cm}^{-3})$ for model 2, respectively.

6.1. Model 1

Figure 10 shows the model spectrum of G0.9+0.1 when the distance to G0.9+0.1 is taken to be 8 kpc together with observational data. We fit the data with the parameters $\eta = 3.0 \times 10^{-3}$, $t_{age} = 2.0$ kyr, $\gamma_{max} = 8.0 \times 10^{8}$, $\gamma_{min} = 4.0 \times 10^{3}$, and $p_2 = 2.6$. The observed radio spectrum is not fitted with the usual value of $p_1$ in a range of $p_1 > 1$ but we take $\gamma_{min} = \gamma_{h0}$. The fitted fraction parameter is close to that of the Crab Nebula, being just 0.6 times the value of the latter. The fitted age $t_{age} = 2.0$ kyr deviates from the characteristic age $\tau_c = 5.3$ kyr, i.e., the current period is close to the initial period. The expansion velocity $v_{PWN} = 1.120 \text{ km s}^{-1}$ is comparable with that of G21.5−0.9 and model 2 of G54.1+0.3. The pulsar parameters are $t_0 = 3.2$ kyr, $L_0 t_0 = 1.2 \times 10^{50}$ erg, and the current total energy $E_{tot}(2.0 \text{ kyr}) = 4.4 \times 10^{48}$ erg, which is almost half of $L_0 t_0$. The current magnetic field strength of G0.9+0.1 turns out to be $B_{now} = 15 \mu G$.

A single power-law injection describes the observations well. The radio emission comes from the particles suffering from the adiabatic cooling and details are given in Section 7.1. The $\gamma$-ray emission is observed by the IC/IR and IC/OPT. The synchrotron cooling break frequency $\nu_c \sim 5 \times 10^{16}$ Hz corresponds to the flux peak.

Figure 11 shows the evolution of the emission spectrum (left panel) and the particle distribution (right panel) of G0.9+0.1
using the same parameters as in Figure 11. While the synchrotron flux decreases, the inverse Compton flux increases with time. This feature is the same as in G21.5−0.9 because the spin-down time $\tau_0 = 3.2 \text{ kyr}$ is large. In the right panel, we see how a single power-law distribution evolves with time, producing the low-energy tail.

### 6.2. Model 2

Figure 12 shows the model spectrum of G0.9+0.1 when the distance to G0.9+0.1 is taken to be 13 kpc together with observational data. We fit the data with the parameters $\eta = 1.0 \times 10^{-3}$, $t_{\text{age}} = 4.5 \text{ kyr}$, $\gamma_{\text{max}} = 1.0 \times 10^{9}$, $\gamma_{\text{b}} = \gamma_{\text{min}} = 1.0 \times 10^{3}$, and $p_2 = 2.6$. The fraction parameter is similar to that of model 1. The main difference is in the fitted age of G0.9+0.1, which is more than twice that of model 1, because given the larger distance to the object we need a larger current total energy $E_{\text{tot}}$. The expansion velocity $v_{\text{PWN}} = 830 \text{ km s}^{-1}$ is slightly smaller than that in model 1. The pulsar parameters of G0.9+0.1 are $t_0 = 0.8 \text{ kyr}$ and $L_0 t_0 = 4.8 \times 10^{49} \text{ erg}$. The current total energy $E_{\text{tot}}(4.5 \text{ kyr}) = 4.2 \times 10^{49} \text{ erg}$ is an order of magnitude larger than that in model 1. Note that $t_{\text{age}}$ is larger than $t_0$ for model 2 and vice versa for model 1. The current magnetic field strength $B_{\text{now}} = 12 \mu \text{G}$ is similar to model 1.

The $\gamma$-ray emission is dominated by the IC/IR component. Although the energy density of the ISRF is very different from that in model 1, the energy density of the magnetic field remains similar because of the strong Klein–Nishina effect on the IC/OPT in model 1. Note that the difference of the ISRF energy density between models 1 and 2 is mainly in the optical band. The synchrotron cooling break frequency is $\nu_{\text{c}} \sim 2 \times 10^{15} \text{ Hz}$.

Figure 13 shows the evolution of the emission spectrum (left panel) and the particle distribution (right panel) of G0.9+0.1 using the same parameters as in Figure 13 (model 2). Both the synchrotron flux and the IC flux decrease with time, and this behavior is the same as in G54.1+0.3 which is shown in the left panel of Figure 5. This different evolution in the left panels of Figures 11 and 13 arises from the difference between $t_{\text{age}}$ and $t_0$ in the models.
6.3. Discussion

Both models 1 and 2 reproduce the observed spectra well and both models are acceptable. The models differ in the IC/OPT flux, but the current observations cannot distinguish the models. A low-energy, power-law component for the injected particles is not needed (see the injection spectrum in the right panels of Figures 11 and 13) to reproduce the observed radio spectrum of G0.9+0.1. This is because the adiabatic cooling of the injected particles can create the observed radio spectrum as will be discussed in Section 7.1. However, we note that no other PWNe we have studied can be fitted by the single power-law injection of the particles.

Fang & Zhang (2010) studied the spectral evolution of G0.9+0.1. They adopted the model in which G0.9+0.1 is located at the Galactic center \( (d = 8.5 \text{kpc in their model}) \) with similar values of the ISRF energy densities \( U_{\text{IR}} = 0.5 \text{ eV/cm}^3 \) and \( U_{\text{opt}} = 20 \text{ eV/cm}^3 \) to our model 1. The most interesting point in their model is that the particle distribution at injection is given by a relativistic Maxwellian distribution plus a single power-law distribution (e.g., Spitkovsky 2008), not a broken power-law distribution. They could reproduce the observed spectrum of G0.9+0.1 with \( p_2 = 2.5 \) and \( \eta_b \sim 4 \times 10^4 \). The current magnetic field strength 8.1 \( \mu \text{G} \) is about half of our value \( B_{\text{now}} = 15 \mu \text{G} \). As will be discussed in Section 7.1, their conclusion is consistent with our study, but the existence of the relativistic Maxwellian component is not essential for reproducing the observed radio spectrum. Note that adiabatic cooling of the injected particles could also work in their model to reproduce the observed radio spectrum.

7. DISCUSSION AND CONCLUSIONS

We first discuss the dependence of the emission spectrum on the adopted ISRF energy densities. Next, we discuss the differences and similarities in the fitted and derived parameters among five young TeV PWNe including the Crab Nebula. We search for correlations between the central pulsar properties and the fitted parameters.

7.1. General Discussion

There is a possibility that the ISRF energy density is locally different from the mean values of the Galaxy as discussed in the case of model 2 of G54.1+0.3 and we see that the \( \gamma \)-ray emission is dominated by the IC/ISRF except for the Crab Nebula. To reproduce the observed power of the IC/ISRF, a larger ISRF energy density \( U_{\text{ISRF}} \) leads to a smaller current total energy of particles \((1 - \eta) E_{\text{tot}}(t_{\text{age}})\). Accordingly, the fraction parameter \( \eta \) needs to be larger to reproduce the observed power of the synchrotron radiation. We showed in our previous paper (Section 3.3 of Tanaka & Takahara 2010) that the power of the synchrotron radiation and that of the IC/ISRF roughly behave as \( P_{\text{syn}} \propto (1 - \eta) \eta E_{\text{tot}}^2 \) and \( P_{\text{IC/ISRF}} \propto (1 - \eta) E_{\text{tot}} U_{\text{ISRF}} \), respectively. These relations lead to \( E_{\text{tot}} \propto U_{\text{ISRF}}^{-1} \) and \( \eta \propto U_{\text{ISRF}}^{-1} \) together with observed \( P_{\text{syn}} \) and \( P_{\text{IC/ISRF}} \). As for \( t_{\text{age}} \), we find that a larger \( U_{\text{ISRF}} \) leads to a smaller \( t_{\text{age}} \) from the integration of Equation (1).

However, the Klein–Nishina effect makes the dependence of \( E_{\text{tot}} \) and \( \eta \) on \( U_{\text{ISRF}} \) somewhat milder. As seen in Table 1, the adopted \( U_{\text{IR}} \) in model 2 of G54.1+0.3 is four times larger than that in model 1, but the \( E_{\text{tot}} \) of model 1 is about three times larger than that of model 2. Accordingly, \( \eta \) of model 2 is about seven times larger than that of model 1. In Section 5.3, we considered how large an \( U_{\text{ISRF}} \) is required in order for the \( \eta \) of Kes 75 to be as large as other PWNe. We can estimate that more than an order of magnitude larger \( U_{\text{ISRF}} \) is required for model 1 and an almost two orders of magnitude larger \( U_{\text{ISRF}} \) is required for model 2.

For the fraction parameter \( \eta \), all the young TeV PWNe have a value much smaller than unity and most of them are similar to each other. We conclude that the fraction parameter \( \eta \) in our model is typically a few \( \times 10^{-3} \) for young TeV PWNe except for Kes 75.

For the break energy, \( \gamma_b \sim 10^{3-5} \) is found for all the young TeV PWNe. Together with the minimum energy \( \gamma_{\text{min}} \) and the low-energy power-law index at injection \( p_1 \), these parameters determine the supply rate of the particles from the pulsar wind and thus determine the pair multiplicity \( \kappa \) inside the pulsar magnetosphere and the bulk Lorentz factor of the pulsar wind \( \Gamma_w \) (Tanaka & Takahara 2010; Bucciantini et al. 2011). For the typical values of the power-law indices at injection \( 1 < p_1 < 2 < p_2 < 3 \), the particle number flux is estimated as \( N_{\text{inj}}(t) \sim \gamma_{\text{min}} Q_{\text{inj}}(\gamma_{\text{min}}, t) \) and the particle energy flux is estimated as \( E_{\text{part}}(t) \sim \gamma_b^2 m_e c^2 Q_{\text{inj}}(\gamma_b, t) \). We can estimate \( \kappa \) as \( \kappa = n_{\text{GJ}} \), where \( n_{\text{GJ}} \) is the Goldreich–Julian number flux and \( \Gamma_w \) is estimated as \( L(t) \sim E_{\text{part}}(t) \sim N_{\text{inj}}(t) \Gamma_w m_e c^2 \).
fitted minimum energy ($\gamma_{\text{min}} < a \times 10^3$) gives a lower limit of $\kappa$ and an upper limit of $\Gamma_w$. However, the values of $\kappa$ and $\Gamma_w$ of G0.9+0.1 are fixed because $\gamma_{\text{min}} = \gamma_b$. Derived $\kappa$ and $\Gamma_w$ for each PWN are listed in Table 2. We find that the lower limit of $\kappa$ is larger than $10^4$ for all young TeV PWNe and that the upper limit of $\Gamma_w$ is smaller than $\gamma_b$ for the Crab Nebula and Kes 75 (models 1 and 2). These quantities may be more constrained by the future lowest-frequency radio observations such as LOFAR, ASKAP, and SKA.

The high-energy power-law index at injection $p_2 \sim 2.5$ takes a very similar value for all five young TeV PWNe. As stressed by Bucciantini et al. (2011), spatially variable fluxes and photon indices of X-ray observations are not guaranteed to be reproducible in one-zone broadband emission models. For example, the hard X-ray observation of Kes 75 may suggest that the hard X-ray emission mainly comes from the central region of strong magnetic fields. However, the result of $p_2 \sim 2.5$ for all the young TeV PWNe is still interesting. It suggests that the acceleration process at the pulsar wind termination shock and/or the cooling, advection, and diffusion of the accelerated particles is common to young PWNe (e.g., Bamba et al. 2010).

The low-energy power-law index at injection $p_1$, on the other hand, is different for each PWN and varies $1.0 \leq p_1 \leq 1.6$. Moreover, in the case of G0.9+0.1, we either do not need a low-energy component or it should be very hard ($p_1 < 1.0$). On the assumption of a uniform PWN, this behavior of G0.9+0.1 is explained in the following way. Low-energy particles are mainly cooled by adiabatic cooling. When we take into account only the adiabatic cooling, Green’s function of the continuity equation of particles in energy space

$$\frac{\partial}{\partial t} G(\gamma, t) - \frac{\partial}{\partial \gamma} \left( \frac{\gamma}{t} G(\gamma, t) \right) = \delta(\gamma - \gamma_0) \delta(t - t_0)$$

becomes

$$G(\gamma, t) = \frac{1}{\alpha} \gamma^{-1} \Theta(\gamma_0 - \gamma) \delta \left( \ln \frac{t}{t_0} + \frac{1}{\alpha} \ln \frac{\gamma}{\gamma_0} \right),$$

where $\alpha$ takes into account an accelerated ($\alpha > 1$) or decelerated ($\alpha < 1$) expansion of the PWN ($R_{\text{PWN}} \propto t^n$) and $\Theta(x)$ is the Heaviside step function. For simplicity, we consider the solution of the time-dependent injection $q(\gamma, t) = q_0 (t^{-1})^{-\beta} \delta(\gamma - \gamma_1) \Theta(t - t_1)$, where $q_0 = \text{const}.$ is a normalization factor, $t_1$ is the time when the injection starts, $\gamma_1$ is the particle energy at injection, and $\beta$ is the time dependence of injection. The particle distribution $N(\gamma, t)$ is given by

$$N(\gamma, t) = \frac{q_0 t}{\alpha \gamma_1} \left( \frac{\gamma}{\gamma_1} \right)^{\frac{1}{\alpha} - 1} \left( \frac{t}{t_1} \right)^{-\beta} \Theta(\gamma_1 - \gamma) \times \Theta \left( \gamma - \left( \frac{t}{t_1} \right)^{\alpha} \gamma_1 \right).$$

We consider the PWN expanding at a constant velocity $\alpha = 1$ and the particles whose energy is lower than $\gamma_1 = \gamma_b = \gamma_{\text{min}}$ for G0.9+0.1. Equation (10) gives the particle distribution $N \propto \gamma^{-\beta}$ for $\gamma < \gamma_1 = \gamma_{\text{min}}$. From Equation (1), for $t \ll t_0$, $\beta = 0$ while $\beta = (n + 1)/(n - 1)$ for $t \gg t_0$. However, for $t_{\text{age}} \sim t_0 \sim O(\text{kyr})$, as in both models of G0.9+0.1, $\beta$ smoothly varies from 0 to 2 for $n = 3$ on the timescale of $t_0$. As seen in the right panels of Figures 11 and 13 (see thick dotted curves at 10 kyr), the particle distribution for $\gamma < \gamma_b$ continuously changes from 0 to $-2$ on the timescale of $t_0$. Thus, the observed radio spectral index $\alpha_r = -0.18$ (Dubner et al. 2008), corresponding to the power-law index $\sim -1.4$ of particle distribution, can be almost reproduced by the adiabatic cooling. Note that the slope of the particle distribution for $\gamma < \gamma_b$ is slightly different between the right panels of Figures 11 and 13, because $t_0$ is different. Note also that the observed radio spectral index $\alpha_r = -0.18$ is clearly smaller than $\alpha_r = 1/3$, which corresponds to the low-frequency tail of synchrotron radiation.

Concerning the properties of the central pulsars, when the braking index $n$ is given, the spin-down evolution of the pulsar is characterized by two parameters, the initial spin-down power $L_0$ and the spin-down time $t_0$ in Equation (1). In other words, the individualities of each pulsar come from these two quantities which theoretically represent the two parameters equivalent to the initial rotational energy and the magnetic energy of the pulsar. In Figure 14, we plot the correlation between the initial rotational energy $L_0 t_0$ and the magnetic energy $B_{\text{mag}}^2 R_{\text{pol}}^6/6$ of the central pulsars. Model 1 of G54.1+0.3 and model 2 of Kes 75 are not plotted.
unchanged even if we use the canonical value $n = 3$ for Kes 75, instead of using $n = 2.65$. Although the canonical value $n = 3$ keeps $E_B$ unchanged from its birth, when $n$ is not 3, it seems better to use the initial value of $E_B$ ($E_{B0}$) rather than that at the present time $E_B(t_{age})$. However, for Kes 75 ($n = 2.65$), $E_B(t_{age})$ is only a factor of 1.3 smaller than $E_{B0}$. The value of $n$ also changes $L_0$ $t_0$. However, $L_0$ $t_0$ for $n = 2.65$ is only a factor of 1.4 larger than that for $n = 3$ with fixed $E_{tot}(t_{age})$, which we can almost independently determine from the observed power of the IC/ISRF.

We also search for correlations between the parameters of the injection spectrum and the pulsar parameters. The pulsar parameters include the spin-down power $L(t) \propto P/P^3$, the surface dipole magnetic field $B_0 \propto P^{1/2}/P^{1/2}$, the potential difference at the polar cap $\Phi_{pole} \propto B(R)c/\Omega c^3 \propto P^{1/2}/P^{5/2}$, where $\Omega$ is the current angular velocity of the pulsar. In Figure 15 (left), we plot the correlation between the fraction parameter $\eta$ and the light cylinder magnetic field $B_{lc}$. Although it seems to show some correlation, when we ignore Kes 75, the correlation is insignificant and the values of $\eta$ for the other objects spread only in a range $10^{-3} - 10^{-2}$. In Figure 15 (right), we plot the correlation between the maximum energy $\gamma_{max}$ and the potential difference at the polar cap $\Phi_{pole}$. Because $\Phi_{pole}$ gives the maximum available electric energy of the pulsar to accelerate particles, this correlation is expected as mentioned by Bucciantini et al. (2011). However, we do not find a significant correlation. This may be partly because only an upper limit of $\gamma_{max}$ is obtained, except for the Crab Nebula. For other combinations of the parameters, we do not find any significant correlations and we do not show them here.

Lastly, we discuss the age $t_{age}$ and the expansion velocity $v_{PWN}$ of PWNe. Our spectral evolution model can estimate the age of the central pulsar in a fairly reliable way from the observed power of the IC/ISRF. In contrast, when the spin-down time $t_0$ is close to the age of the pulsar $t_{age}$ as seen in Equation (2), the characteristic age $\tau_c$ of a pulsar is not guaranteed to match the age of young pulsars. For example, $\tau_c$ of the central pulsars inside the Crab Nebula and G21.5–0.9 are 1.2 kyr and 4.8 kyr, but $t_{age}$ fitted with our model and the ages estimated from the observed expansion rate of the synchrotron nebula are both ~1.0 kyr.

We discuss the properties of the SN explosion which creates the pulsars with obtained $v_{PWN}$ and $E_{tot}$. Simply, we expect the relation $v_{PWN} \sim (E_{tot}(t)/E_{SN})^{0.2}v_{SN}$, where $E_{SN}$ is the energy of SN ejecta and $v_{SN}$ is the velocity of the front of the freely expanding ejecta. We derive this relation from the radius of PWNe $R_{PWN}$ in a freely expanding SN ejecta estimated as $R_{PWN}(t) \sim (E_{tot}(t)/E_{SN})^{0.2}v_{SN}$ by van der Swaluw et al. (2001). We do not find the relation $v_{PWN} \propto E_{tot}^{0.2}$, which suggests that the values of $E_{SN}$ and $v_{SN}$ are not common to the PWNe. On the other hand, because the derived values of $v_{PWN}$ and $E_{tot}^{0.2}$ differ by a factor of a few, the combination of $v_{SN}/E_{SN}^{0.2}$ also ranges within a factor of a few.

7.2. Conclusions

In this paper, we apply our spectral evolution model to four young TeV PWNe, G21.5–0.9, G54.1+0.3, Kes 75, and G0.9+0.1. Based on this rather simplified one-zone model, we have succeeded in reproducing many observed properties of these PWNe.

The current observed spectra of all four young TeV PWNe are reconstructed with small values of the fraction parameter $\eta \ll 1$ as well as the Crab Nebula, i.e., the magnetic energy of these PWNe accounts for a very small fraction of the current total energy injected into the PWN $E_{tot}(t_{age})$. The fitted fraction parameters are typically a few $10^{-3}$ except for those of Kes 75. The fraction parameter of the peculiar object Kes 75 is more than two orders of magnitude smaller than the typical value.

The TeV $\gamma$-ray emission from the young TeV PWNe is dominated by IC/ISRF. Since the energy density of the local ISRF around the objects is somewhat uncertain, it is important to take into account its effect as considered in model 2 of G54.1+0.3. On the other hand, the $\gamma$-ray emission at an early phase of their evolution (e.g., $t_{age} < 300$ yr) is always SSC dominant because the magnetic energy density of the PWN is much larger than the local ISRF energy density.

A broken power-law injection of particles reproduces the observed spectrum well from radio to TeV $\gamma$-rays, except in

Figure 15. Correlations between the fraction parameter $\eta$ vs. the magnetic field strength at the light cylinder $B_{lc}$ (left panel) and the maximum energy $\gamma_{max}$ (lower limit except for the Crab Nebula) versus the potential difference at polar cap $\Phi_{pole}$ (right panel). Model 1 of G54.1+0.3 and model 2 of Kes 75 are not plotted.
the case of G0.9+0.1 where we do not need the low-energy component. The observed spectrum of G0.9+0.1 in radio is created by the adiabatic cooling of the high-energy component of the injected particles.

The fitted break energy $\gamma_b \sim 10^5$ is rather common. On the other hand, the fitted maximum energy $\gamma_{\text{max}}$ is a lower limit (more than $10^8$) and the fitted minimum energy $\gamma_{\text{min}}$ is an upper limit (less than $10^4$). The high-energy power-law index at injection $p_2 \sim 2.5$ is common for all young TeV PWNe, while the low-energy power-law index at injection $p_1$ varies in the range $1.0 \leq p_1 \leq 1.6$.

The fitted parameters of the injection spectrum in Equation (4) give a lower limit of the pair multiplicity $\kappa$, which turns out to be more than $10^2$. We have also estimated an upper limit of the bulk Lorentz factor of the pulsar wind $\Gamma_w$. For G21.5−0.9 and G54.1+0.3, the upper limit of $\Gamma_w$ is still consistent with $\gamma_b$, but the obtained $\Gamma_w$ of Kes 75 is clearly less than $\gamma_b$. The latter feature is the same as for the Crab Nebula in our previous work (more than $10^9$) and the fitted minimum energy $\gamma_{\text{min}}$ is still consistent with $\gamma_b$ without uncertainty in our model.

From the fitted age, we can derive the initial spin-down luminosity and the spin-down time of the central pulsar. We take the initial rotational energy $L_0 \tau_0$ and the magnetic energy $E_B$ of the pulsar as two independent parameters which characterize the spin-down evolution of the pulsar and search for a correlation between them. They seem to be anticorrelated, although the statistics are rather poor. We also search for correlations between the fraction parameter and the parameters of the injection spectrum versus the central pulsar properties. However, we find no significant correlations.

We are grateful to Y. Ohira for useful discussions. We thank the anonymous referee for a meticulous reading of the manuscript and helpful comments. This work is partly supported by KAKENHI (F.T., 20540231) and JSPS Research Fellowships for Young Scientists (S.T., 23250).
