We study the QCD phase diagram at finite temperature and baryon chemical potential by relating the behavior of the light-quark condensate to the threshold energy for the onset of perturbative QCD. These parameters are connected to the chiral symmetry restoration and the deconfinement phase transition, respectively. This relation is obtained in the framework of finite energy QCD sum rules at finite temperature and density, with input from Schwinger-Dyson methods to determine the light-quark condensate. Results indicate that both critical temperatures are basically the same within some 3% accuracy. We also obtain bounds for the position of the critical end point, $\mu_B \gtrsim 300$ MeV and $T_c \lesssim 185$ MeV.

I. INTRODUCTION

In Quantum Chromodynamics (QCD) the strong interaction among quarks depends on their color charge. When quarks are placed in a medium this color charge is screened with increasing density. The density can increase either by raising the temperature, so that collisions between quarks produce more quarks and gluons, or by compressing the system, thereby increasing the baryon density. If the density increases beyond a certain critical value one expects that the interactions between quarks no longer confine them inside a hadron, so that they are free to travel longer distances and deconfine. This transition from a confined to a deconfined phase is usually referred to as the deconfinement phase transition.

A separate phase transition takes place when the realization of chiral symmetry shifts from a Nambu-Goldstone phase to a Wigner-Weyl phase. In the massless quark limit this is achieved by the vanishing of the quark condensate, or alternatively the pion decay constant. Qualitatively, one expects these two phase transitions to take place at approximately the same temperature. An outstanding issue is whether this conclusion also holds quantitatively. To address this, it has been customary to study the behavior of the order parameters of these transitions as functions of the temperature $T$ and the baryon chemical potential $\mu_B$, namely the Polyakov loop $L^2$ and quark anti-quark condensate $\langle \bar{\psi} \psi \rangle$ in the chiral limit, respectively. In the confined phase the former parameter either vanishes in the limit of massless quarks, or else it is exponentially suppressed for finite quark masses, while it is finite in the deconfined phase. The quark condensate is finite in the confined phase, while it vanishes in the deconfined phase at high enough temperature, and in the limit of massless quarks. For finite quark masses chiral symmetry is explicitly broken at the Lagrangian level and therefore the phase transition is suppressed. This is similar to what happens to a ferromagnet in the presence of an external magnetic field. In this situation one might need to specify to what extent one is still dealing with a phase transition.

At finite $T$, and $\mu_B = 0$, lattice QCD calculations provide a consistent quantitative picture of the above behavior, resulting in similar critical temperatures $T_c$ for both transitions in the range $170 \text{ MeV} \lesssim T_c \lesssim 200 \text{ MeV}$, for finite quark masses $\gtrsim 300 \text{ MeV}$. The situation is much less clear cut when both $T$ and $\mu_B$ are simultaneously non-zero. Lattice QCD simulations cannot be used for $\mu_B \neq 0$ because the fermion determinant becomes complex and thus standard Monte Carlo methods fail, as the integrand is no longer real and positive definite. However, these techniques can still be adapted to extract some, though not exact, information on the QCD phase diagram for $\mu_B \neq 0$. Therefore, one needs to resort either to mathematical constructions to overcome the above limitation, or to model calculations. Of particular recent interest is the search for a possible critical end point that signals the strengthening of the order of the transition with increasing $\mu_B$, indicating the beginning of a true chiral symmetry restoring/deconfining phase transition. The results from Monte Carlo simulations and model calculations, with and without Polyakov loop, or its variants, seem to be in conflict. In fact, the former give smaller (larger) values for the end point baryon chemical potential (temperature) than the latter. Things become worse if one uses the imaginary chemical potential method, a well established technique for not too large values of $\mu_B$. Indeed, this leads to a shrinking and weakening region of chiral phase transitions with increasing $\mu_B$, thus suggesting that there is no critical end point for $\mu_B \lesssim 500 \text{ MeV}$.
the existence of the critical end point would not be ruled out, although it would require a non-monotonic behavior \[11\]. In view of this situation, alternative ways of examining the QCD phase diagram are required.

One possibility is to look at variables that describe deconfinement other than the Polyakov loop. A phenomenological QCD parameter associated with deconfinement was first proposed long ago in \[12\], and it is the square energy \( s_0 \) beyond which the hadronic resonance spectral function becomes smooth and well described by perturbative QCD (PQCD). At \( T = 0 \) this continuum threshold lies in the range \( s_0 \simeq 1 - 3 \) GeV\(^2\), depending on the channel. At finite temperature one expects \( s_0 \) to decrease with increasing \( T \) and approach the kinematical threshold at some critical value \( T = T_c \), to be identified with the deconfinement temperature. In this scenario one expects stable particles (poles on the real axis in the complex squared energy \( s \)-plane) to develop a width as a result of absorption in the thermal bath. At the same time, resonances (poles in the second Riemann sheet in the complex \( s \)-plane) should develop \( T \)-dependent widths, increasing with increasing temperature. Such a resonance broadening mechanism was first proposed in detail in connection with dimuon production in heavy ion collisions \[13\].

The natural framework to determine \( s_0 \) has been that of QCD sum rules \[14\]. This quantum field theory framework is based on the operator product expansion (OPE) of current correlators at short distances, extended beyond perturbation theory, and on Cauchy’s theorem in the complex \( s \)-plane. The latter is usually referred to as quark-hadron duality. Vacuum expectation values of quark and gluon field operators effectively parametrize the effects of confinement. An extension of this method to finite temperature was first outlined in \[12\]. Further evidence supporting the validity of this program was provided in \[15\], followed by a large number of applications \[16-17\]. Of particular interest to the present work are the results obtained for \( s_0(T) \) in \[16\] using QCD Finite Energy Sum Rules (FESR) for the (light-quark) axial-vector current correlator. The leading dimension FESR relates \( s_0(T) \) to the pion decay constant \( f_\pi(T) \), and this in turn to the light-quark condensate (using the Gell-Mann-Oakes-Renner relation \[18\]). In the chiral limit it was found that \( s_0(T)/s_0(0) \simeq f_\pi(T)/f_\pi(0) \simeq \langle \bar{\psi} \gamma^\mu \psi(T)/\langle \bar{\psi} \gamma^\mu \psi \rangle \rangle \) holds to a very good approximation. This relation hints towards the possible coincidence of the critical temperatures for deconfinement and chiral-symmetry restoration. In this paper we extend this analysis to finite density, thus obtaining \( s_0(T, \mu_B) \) from FESR using as input the light-quark condensate at finite temperature and density determined in the Schwinger-Dyson equations (SDE) framework.

The paper is organized as follows: In Sec. \[III\] we find the relation between the quark condensate and the PQCD threshold \( s_0 \) using FESR for the axial-vector current correlator. In Sec. \[IV\] we compute the quark condensate at finite \( T \) and \( \mu_B \) from a convenient parametrization of the quark propagator in the SDE framework. In Sec. \[V\] we present our analysis of the QCD phase diagram and show that the deconfinement and chiral symmetry restoration transitions take place at basically the same temperature to some 3\% accuracy, i.e. within the numerical precision of the method. We finally summarize and discuss our results in Sec. \[VI\].

II. Finite Energy QCD Sum Rules

We begin by considering the (charged) axial-vector current correlator at \( T = 0 \)

\[
\Pi_{\mu\nu}(q^2) = i \int d^4x e^{iqx} \langle 0|T(A_\mu(x)A_\nu(0))|0\rangle = -g_{\mu\nu} \Pi_1(q^2) + q_\mu q_\nu \Pi_0(q^2),
\]

(1)

where \( A_\mu(x) = \bar{u}(x)\gamma_\mu \gamma_5 d(x) : \) is the axial-vector current, \( q_\mu = (\omega, \vec{q}) \) is the four-momentum transfer, and the functions \( \Pi_0(q^2) \) are free of kinematical singularities. Concentrating on the function \( \Pi_0(q^2) \) and writing the OPE beyond perturbation theory in QCD \[14\], one of the two pillars of the sum rule method, one has

\[
\Pi_0(q^2)|_{QCD} = C_0 \hat{f} + \sum_{N=1} C_{2N}(q^2, \mu^2) \langle \hat{O}_{2N}(\mu^2) \rangle,
\]

(2)

where \( \mu^2 \) is a renormalization scale, the Wilson coefficients \( C_N \) depend on the Lorentz indices and quantum numbers of the currents and on the local gauge invariant operators \( \hat{O}_N \) built from the quark and gluon fields in the QCD Lagrangian. These operators are ordered by increasing dimensionality and the Wilson coefficients, calculable in PQCD, fall off by corresponding powers of \(-q^2\). The unit operator above has dimension \( d = 0 \) and \( C_0 \hat{f} \) stands for the purely perturbative contribution. Hence, this OPE factorizes short distance physics, encapsulated in the Wilson coefficients, and long distance effects parametrized by the vacuum condensates. The second pillar of the QCD sum rule technique is Cauchy’s theorem in the complex squared energy \( s \)-plane

\[
\frac{1}{\pi} \int_0^{s_0} ds f(s) \text{Im} \Pi_0(s) = -\frac{1}{2\pi i} \oint_{C(|s|) = s_0} ds f(s) \Pi_0(s),
\]

(3)

where \( f(s) \) is an arbitrary analytic function, and the radius of the circle \( s_0 \) is large enough for QCD and the OPE to be used on the circle (see Fig.1). The integral along the real \( s \)-axis involves the hadronic spectral function. This equation is the mathematical statement of what is usually referred to as quark-hadron duality. Using the OPE, Eq. (2), and an integration kernel
not too high, say leading order in PQCD, as long as the temperature is major loss of accuracy in results from thermal FESR to radiative corrections at $T \lesssim 0.1 T$. One new feature at order in PQCD, thus implying a systematic uncertainty the appearance of a new cut in the complex energy $s$-plane. However, there is no evidence for such a term (at $T = 0$) from FESR analyses of experimental data on $e^+e^-$ annihilation and $\tau$ decays into hadrons \[19\]. At very high temperatures, though, there seems to be evidence for some $d = 2$ term \[20\]. However, the analysis to be reported here is performed at much lower values of $T$, so that we can safely ignore this contribution in the sequel.

The extension of this program to finite temperature is fairly straightforward \[12, 15\], with the Wilson coefficients in the OPE, Eq. \[3\], remaining independent of $T$ at leading order in $\alpha_s$, and the condensates developing a temperature dependence. Radiative corrections in QCD involve now an additional scale, i.e. the temperature, so that $\alpha_s \equiv \alpha_s(\mu^2, T)$. This problem has not yet been solved successfully. Nevertheless, from the size of radiative corrections at $T = 0$ one does not expect any major loss of accuracy in results from thermal FESR to leading order in PQCD, as long as the temperature is not too high, say $T \lesssim 200$ MeV. Essentially all applications of FESR at $T \neq 0$ have been done at leading order in PQCD, thus implying a systematic uncertainty at the level of 10%. One new feature at $T \neq 0$ is the appearance of a new cut in the complex energy $\omega$-plane \[12\], and centered at the origin with extension $-|\vec{q}| \leq \omega \leq |\vec{q}|$. This is due to a contribution to the current correlator in the space-like region ($q^2 < 0$) which vanishes at $T = 0$. Conceptually, this originates in the scattering of the current by either quarks (antiquarks) or by hadrons in the medium, in the case of QCD or the hadronic representation, respectively. When considering the rest-frame ($\vec{q} \to 0$) this scattering term either becomes a delta function of the energy or it vanishes identically, depending on the channel. For instance, in the case of the axial-vector current correlator, Eq. \[4\], the QCD scattering term is proportional to $\delta(\omega^2)$. The corresponding term in the hadronic representation is non-zero but it is suppressed relative to the tree-level pion contribution, as the axial-vector current can only couple to an odd number of pions. Another new feature at finite temperature is the possible existence of non-scalar (Lorentz noninvariant) vacuum condensates. This does not affect the present analysis, as we shall only consider dimension $d = 2$ FESR.

In the static limit ($\vec{q} \to 0$), to leading order in PQCD, and for $T \neq 0$ and $\mu_B \neq 0$ the function $\Pi_0(q^2)$ in Eq. \[1\] becomes $\Pi_0(\omega^2, T, \mu_B)$; to simplify the notation we shall omit the $T$ and $\mu_B$ dependence in the sequel. A straightforward calculation of the spectral function in perturbative QCD gives

$$\left[ 1 - \frac{\tilde{n}_+ \left( \sqrt{s} \right)}{2} - \frac{\tilde{n}_- \left( \sqrt{s} \right)}{2} \right]$$

$$\frac{1}{\pi^2} \left[ \left( \frac{\tilde{B}_2(\omega^2/\mu^2)}{} \right) \right], \quad (5)$$

where $\tilde{B}_2(x)$ is the dilogarithm function, $s = \omega^2$, and

$$\frac{1}{\pi^2} \left[ \left( \frac{\tilde{B}_2(\omega^2/\mu^2)}{} \right) \right], \quad (6)$$

are the Fermi-Dirac thermal distributions for particles and antiparticles, respectively. We have assumed massless quarks, as quark mass corrections are negligible. However, later when we determine the quark condensate in Section III this approximation will be relaxed.

In the limit where $T$ and/or $\mu_B$ are large, Eq. \[5\] becomes

$$\left[ 1 - \frac{\tilde{n}_+ \left( \sqrt{s} \right)}{2} - \frac{\tilde{n}_- \left( \sqrt{s} \right)}{2} \right]$$

$$\frac{1}{\pi^2} \left[ \left( \frac{\tilde{B}_2(\omega^2/\mu^2)}{} \right) \right], \quad (7)$$

In the hadronic sector we assume pion-pole dominance of the hadronic spectral function, i.e. the continuum threshold $s_0$ to lie below the first radial excitation with mass $M_{\pi_1} \simeq 1300$ MeV. This is a very good approximation at finite $T$, as we expect $s_0$ to be monotonically decreasing with increasing temperature. In this case,

$$\frac{1}{\pi} \left[ \left( \frac{\tilde{B}_2(\omega^2/\mu^2)}{} \right) \right], \quad (8)$$
where $f_\pi(T, \mu_B)$ is the pion decay constant at finite $T$ and $\mu_B$, with $f_\pi(0, 0) = 92.21 \pm 0.14$ MeV [21].

Turning to the FESR, Eq. (4), with $N = 1$ and no dimension $d = 2$ condensate, and using Eqs. (5) and (8) one finds
\[
\int_{0}^{s_0(T, \mu_B)} ds \left[ 1 - \bar{n}_+ \left( \frac{\sqrt{s}}{2} \right) - \bar{n}_- \left( \frac{\sqrt{s}}{2} \right) \right] = 8f_\pi^2(T, \mu_B) - 8T^2 \left[ \text{Li}_2(-e^{\mu_B/T}) + \text{Li}_2(-e^{-\mu_B/T}) \right].
\]

This is a transcendental equation determining $s_0(T, \mu_B)$ in terms of $f_\pi(T, \mu_B)$. The latter is related to the light-quark condensate through the Gell-Mann-Oakes-Renner relation [18]
\[
f_\pi^2(T, \mu_B) = \frac{\langle \bar{\psi}\psi \rangle(T, \mu_B)}{\langle \bar{\psi}\psi \rangle(0, 0)},
\]
where the quark and pion masses have been assumed independent of $T$ and $\mu_B$ [22]. A good closed form approximation to the FESR, Eq. (9), for large $T$ and/or $\mu_B$ is obtained using Eq. (10) with $ar{n}_+ \left( \frac{\sqrt{s}}{2} \right) \simeq \bar{n}_- \left( \frac{\sqrt{s}}{2} \right) \simeq 0$, in which case
\[
s_0(T, \mu_B) \simeq 8\pi^2 f_\pi^2(T, \mu_B) - \frac{4}{3} \pi^2 T^2 - 4\mu_B^2.
\]

Using Eq. (10) this can be rewritten as
\[
s_0(T, \mu_B) \simeq \frac{\langle \bar{\psi}\psi \rangle(T, \mu_B)}{\langle \bar{\psi}\psi \rangle(0, 0)} - \frac{(T^2/3 - \mu_B^2/\pi^2)}{2f_\pi^2(0, 0)}.
\]

The quark condensate can be computed from the intermediate quark propagator, whose non-perturbative properties can be obtained e.g. from known solutions to the Schwinger-Dyson equations (SDE) as discussed in the next section.

![Graph showing Lattice data and parametrization of the absolute value of the quark condensate as a function of $T$ in the phase transition region.](image)

**FIG. 2**: (Color online) Lattice data and parametrization of the quark condensate as a function of $T$ in the phase transition region.

TABLE I: Parameters $m_i$ and $r_i$, $i = 1, 2, 3$ to describe the Lorentz covariant part of the quark propagator.

| $i$ | $m_i$ (GeV) | $r_i$ |
|-----|-------------|-------|
| 1   | -0.490      | -0.112|
| 2   | 0.495       | 0.352 |
| 3   | -0.879      | 0.259 |

**III. QUARK PROPAGATOR AND CONDENSATE**

The quark condensate can be computed from the quark propagator $S(k_0, \vec{k})$ in Euclidean space. At finite $T$ and $\mu_B$ the condensate is given by
\[
\langle \bar{\psi}\psi \rangle(T, \mu_B) = -N_c T \sum_n \int \frac{d^3k}{(2\pi)^3} \times \text{Tr} S([2n + 1]T + i\mu_B, \vec{k})
\]
\[
= -N_c T \sum_n \int \frac{d^3k}{(2\pi)^3} \text{Tr} S(k_0, \vec{k}) \times \delta[k_0 - (2n + 1)T - i\mu_B].
\]

Introducing the Poisson summation formula
\[
\sum_l (-1)^l \exp\{i(k_0 + \mu_B)l/T\} = (2\pi) T \sum_n \delta[k_0 - (2n + 1)T - i\mu_B],
\]
leads to
\[
T \sum_n \int \frac{d^3k}{(2\pi)^3} \text{Tr} S([2n + 1]T + i\mu_B, \vec{k}) = \sum_l (-1)^l \int \frac{d^3k}{(2\pi)^3} \text{Tr} S(k_0, \vec{k}) \exp\{i(k_0 + \mu_B)l/T\}.
\]
Using this result in Eq. (10) gives
\[
\langle \bar{\psi}\psi \rangle(T, \mu_B) = -N_c \sum_l (-1)^l \int \frac{d^4k}{(2\pi)^4} \times \text{Tr} S(k_0, \vec{k}) \exp\{i(q_0 + \mu_B)l/T\}.
\]

Notice that from Eq. (10) the vacuum contribution to the condensate comes from the term with $l = 0$. For this we use the value
\[
\langle \bar{\psi}\psi \rangle|_0 = -(0.241 \text{ GeV})^3.
\]
FIG. 3: (Color online) Heat capacity for the quark condensate as a function of $T$ for $\mu_B = 0$ (solid line) and $\mu_B = 300$ MeV (dash line). The critical temperature $T_c$ corresponds to the maximum of the heat capacity for a given value of $\mu_B$.

The true matter contribution to the condensate is thus

$$\langle \bar{\psi} \psi \rangle (T, \mu_B) = -N_c \sum_{l \neq 0} (-1)^l \int \frac{d^4 k}{(2\pi)^4} \times \text{Tr}[S(k_0, \vec{k})] \exp\{(i\nu_0 + \mu_B)l/T\}. \tag{18}$$

Due to the loss of Lorentz covariance at finite $T$ and/or $\mu_B$, the general structure of the propagator is given by

$$S^{-1}(k_0, \vec{k}) = A\gamma_0 k_0 + B\gamma \cdot \vec{k} + C, \tag{19}$$

where $A$, $B$ and $C$ are scalar functions of $k_0$ and $\vec{k}$. They can be obtained from non-perturbative methods such as solutions to SDE. We adopt this procedure here. Motivated by the success of the rainbow-ladder truncation of the SDE and the effective interaction of Ref. [23] in the description of light pseudo-scalar and vector mesons, and the meromorphic representation of the quark propagator [24], we consider the parametrization

$$S(k_0, \vec{k}) = \sum_{i=1}^{3} \left( \frac{r_i}{i\vec{k} + m_i} \right) + \frac{r_4}{i\gamma_0 k_0 + ib\gamma \cdot \vec{k} + m_4}, \tag{20}$$

and choose $b$, the masses $m_i$, and the residues $r_i$, $i = 1 \ldots 3$. The last term in Eq. (20) is added to reproduce the Lorentz covariance breaking effects of the heat bath at $T \neq 0$ and/or $\mu_B \neq 0$. The values of $b$, $m_4$ and $r_4$ are adjusted to reproduce the light-quark condensate as a function of $T$ for $\mu_B = 0$ [see Eq. (21) below] extracted from lattice QCD [4] by means of a point-distance minimization procedure. Carrying out the integrations in Eq. (18), and in terms of the parametrization of the quark propagator

for the parameters $m_i$ and $r_i$, $i = 1 \ldots 3$. The last term in Eq. (20) is added to reproduce the Lorentz covariance breaking effects of the heat bath at $T \neq 0$ and/or $\mu_B \neq 0$. The values of $b$, $m_4$ and $r_4$ are adjusted to reproduce the light-quark condensate as a function of $T$ for $\mu_B = 0$ [see Eq. (21) below] extracted from lattice QCD [4] by means of a point-distance minimization procedure. Carrying out the integrations in Eq. (18), and in terms of the parametrization of the quark propagator

and choose $b$, the masses $m_i$, and the residues $r_i$, $i = 1 \ldots 4$, to be real numbers. In addition we seek $T$-dependent values of $b$, $m_4$ and $r_4$. The Lorentz covariant part of this parametrization is fitted by requiring the propagator to reproduce key features of the rainbow-ladder model [23] at $T = 0$. In particular, to match the ultra-violet behavior of the gap equation for massive $u/d$ quarks, the value of the condensate in vacuum, and the constituent quark masses, as dictated by the of solutions to SDE. Table I shows the values thus obtained

FIG. 4: (Color online) Heat capacity for the PQCD threshold $s_0$ as a function of $T$ for $\mu_B = 0$ (solid line) and $\mu_B = 300$ MeV (dash line). The critical temperature $T_c$ corresponds to the maximum of the heat capacity for a given value of $\mu_B$.

FIG. 5: (Color online) Transition temperatures for the quark condensate and the PQCD threshold $s_0$ as functions of the baryon chemical potential.
in Eq. (20), we obtain

$$\langle \bar{\psi}\psi(T, \mu_B) \rangle_{\text{mat}} = -\frac{8TN_c}{\pi^2} \sum_{l=1}^{\infty} \frac{(-1)^l}{l} \cosh \left( \frac{\mu_B l}{T} \right) \times \sum_{i=1}^{4} \frac{r_i m_i^2}{b_i |\ell|} K_1 \left( \frac{|m_i|}{T} \right),$$  \hspace{1cm} (21)$$

where $K_1(x)$ is a Bessel function, and for convenience we have defined $b_1 = 1$ for $i = 1, 2, 3$, and $b_4 = b$. Figure 2 shows the lattice QCD data for the light quark condensate as a function of $T$ together with the curve obtained from the absolute value of the sum of Eqs. (17) and (21) for $\mu_B = 0$. This parametrization gives a good description of the condensate for the range of temperatures where the phase transition occurs.

IV. QCD PHASE DIAGRAM

With the parametrization of lattice data at finite $T$ and $\mu_B = 0$, we proceed to extend the analysis to finite $\mu_B$. To explore the QCD phase diagram we make use of the expressions for the light-quark condensate and of the PQCD threshold $s_0$ that describe the chiral and deconfinement phase transitions, respectively. We have shown that these quantities are related through a QCD FESR and found that they lead to essentially equal transition temperatures. The quark condensate, and thus the PQCD threshold, is computed using the quark propagator in the SDE framework. We have found it convenient to use a meromorphic parametrization of this propagator in terms of real poles and residues. These are fixed by demanding consistency with the rainbow-ladder truncation of SDE at $T = 0$, and a good description of lattice QCD data for the quark condensate at finite $T$. With this simple scenario we have been able to extend the analysis up to baryon chemical potential $\mu_B \approx 300$ MeV. From our results we can estimate the position of the critical end point to be $\mu_{Bc} \gtrsim 300$ MeV and $T_c \lesssim 185$ MeV, respectively. A more precise location of the critical end point would require a more refined treatment of the parametrization of the quark propagator.

V. DISCUSSION AND CONCLUSIONS

In this paper we have studied the QCD phase diagram at $T \neq 0$ and $\mu_B \neq 0$ based on the behavior of the light-quark condensate and of the PQCD threshold as probes of chiral symmetry restoration and deconfinement, respectively. We have shown that these quantities are related through a QCD FESR and found that they lead to essentially equal transition temperatures. The quark condensate, and thus the PQCD threshold, is computed using the quark propagator in the SDE framework. We have found it convenient to use a meromorphic parametrization of this propagator in terms of real poles and residues. These are fixed by demanding consistency with the rainbow-ladder truncation of SDE at $T = 0$, and a good description of lattice QCD data for the quark condensate at finite $T$. With this simple scenario we have been able to extend the analysis up to baryon chemical potential $\mu_B \approx 300$ MeV. From our results we can estimate the position of the critical end point to be $\mu_{Bc} \gtrsim 300$ MeV and $T_c \lesssim 185$ MeV, respectively. A more precise location of the critical end point would require a more refined treatment of the parametrization of the quark propagator.

VI. ACKNOWLEDGMENTS

We thank E. Cuautle and J. C. Arteaga for useful hints to carry out the parametrization procedure, W. Bietenholz for pointing out useful lattice results, P.C. Tandy for his guidance on how to parametrize the quark propagator and extract quantities such as the condensate from this parametrization and E. Swanson for useful suggestions. Support for this work has been received in part by CONACyT (Mexico) under grant numbers 82230, 128534, CIC-UMSNH 4.10 and 4.22 and PAPIIT-UNAM IN103811-3, FONDECYT 1095217 (Chile), Proyecto Anillos ACT119 (Chile), and NRF (South Africa).

[16] C. A. Dominguez and M. Loewe, Phys. Lett. B 233, 201 (1989). The (near) equality of the critical temperatures for chiral-symmetry restoration and deconfinement was shown analytically in A. Barducci, R. Casalbuoni, S. De Curtis, R. Gatto and G. Pettini, Phys. Lett. B 244, 311 (1990). These authors used a result for the thermal quark condensate valid for $0 \leq T \leq T_c$, while the first reference only made use of the low-T expansion of chiral perturbation theory, obtaining somewhat different critical temperatures.

[17] For recent applications see e.g. C. A. Dominguez, M. Loewe and J.C. Rojas, J. High Energy Phys. 0708, 040 (2007); C. A. Dominguez, M. Loewe, J. C. Rojas, and Y. Zhang, Phys. Rev. D 81, 014007 (2010); ibid. D 83, 034033 (2011), and references therein.
