Abstract

Background: Annual health examination is recommended for the prevention and treatment of cardiovascular diseases and diabetes. However, whether it is effective for the prevention of hyperlipidemia and hyperglycemia remains unclear.

Methods: A retrospective analysis of clinical samples using the laboratory information system was performed. From 2012 to 2019, 5043 participants (1755 males and 3288 females) have completed the annual health examination for 8 consecutive years, which was the follow-up group. In the same period, 136,994 participants (the control group) had a health examination only 1 time. Serum levels of fasting triglyceride (TG), total cholesterol (TC), low density lipoprotein cholesterol (LDL-C), high density lipoprotein cholesterol (HDL-C) and glucose (GLU) were measured.

Results: Compared with 2019 of the control group, serum TC and GLU in the 8th year of the follow-up group increased markedly in some of age groups ($p < 0.001$). Serum TG and TC in the 8th year were much higher compared with the 1st year of the follow-up group, especially for the female ($p < 0.001$). Moreover, the prevalence of hyperlipidemia and hyperglycemia in the 8th year showed significant increase compared with the 1st year of the follow-up group and 2019 of the control group (all $p < 0.05$).

Conclusions: Annual health examination didn’t perform a positive effect in the prevention of hyperlipidemia and hyperglycemia. Health management should be paid more attention to prevent cardiovascular disease and diabetes.
**Background**

Cardiovascular diseases (CVD) have been identified as the first leading disease affecting the Chinese population [1]. It is widely known that serum hyperlipidemia, particularly elevated levels of total cholesterol (TC) and low-density lipoprotein cholesterol (LDL-C), is strongly related with the development of CVD [2]. So, management of serum cholesterol level has been a central objective in preventing cardiovascular events [3].

Over the past three decades, the prevalence of dyslipidemia has increased remarkably in China [4]. The results of 2012 national survey showed that the prevalence of hyperglyceridemia and hypercholesterolemia in adults were 13.1% and 4.9%, respectively [5]. Projected trends in serum TC and other factors would induce an increase of approximately 21.3 million cardiovascular events and 7.7 million cardiovascular deaths over 2010 to 2030 [6]. Therefore, annual health examination was recommended for middle-aged people in the 2016 Chinese guideline for the management of dyslipidemia in adults [7].

Additionally, the prevalence of diabetes was also growing rapidly in China. Almost 25% of middle-aged and elderly rural Chinese residents had diabetes in 2010-2011 [8]. Glucose control can reduce microvascular complication of diabetes mellitus (DM) and may improve clinical outcomes for patients with DM and coronary heart disease [9]. So, early detection of hyperglycemia is necessary for early prevention and treatment of DM.

In recent years, annual health examination for the adults, especially for the middle-aged people and retired elderly, has been carried out in some companies and enterprises for over ten years [10]. Serum lipids and glucose have been detected routinely for all the health check-up people. However, whether annual measurement of serum lipids and glucose is effective for the prevention and treatment of CVD and DM, has not been proved.

**Methods**

**Participants**

All the participants came from the health examination center, Beijing Tongren Hospital, Capital Medical University. From 2012 to 2019, a total of 5043 people (1755 males and 3288 females) had a
health examination for 8 consecutive years, which was the follow-up group. In the same period, the
other people who went for health examination only 1 time were selected to be the control group. All the
participants were divided into 10-year age classes (≤30 years, 31–40 years, 41–50 years, 51–60 years,
61–70 years, ≥71 years).

Measurement
For all the participants, serum levels of TG, TC, LDL-C, HDL-C and GLU were measured after at least
a 12-h overnight fasting. The measurements were performed on a Beckman system (Beckman,
American) in the Department of Clinical Laboratory, Beijing Tongren Hospital. The reagents of serum
TG, TC, LDL-C and HDL-C were provided by the Hitachi Chemical Diagnostics Systems Co., Ltd
(Hitachi Chemical Diagnostics Systems Co., Ltd, Japan). The reagent of serum GLU was provided by
the Beckman (Beckman, American).

Diagnostic criteria
According to the 2016 Chinese guideline for the management of dyslipidemia in adults [7], elevated
levels of TG (≥2.3 mmol/L) and/or TC (≥6.2 mmol/L) in serum were diagnosed as hyperlipidemia.
According to the criteria of Chinese diabetes society [11], increased fasting serum glucose (≥7.0
mmol/L) was defined as hyperglycemia.

Approaches for evaluating the effectiveness of annual health examination to hyperlipidemia and
hyperglycemia control
In our study, evaluation approaches were in accordance with the three strategies used to evaluate the
effectiveness of consecutive health examination, proposed by the Gan W [12]. 1) Concentrations: a.
Compare the levels of serum TG, TC and GLU between the 8th year of the follow-up group and 2019
of the control group; b. Compare the levels of serum TG, TC and GLU between the 1st and the 8th
health examination year of the follow-up group. 2) Prevalence: a. Compare the prevalence of
hyperlipidemia and hyperglycemia between the 8th year of the follow-up group and 2019 of the control
group; b. Compare the prevalence of hyperlipidemia and hyperglycemia between the 1st and the 8th
health examination year of the follow-up group. 3) Calculate the numbers of participants who had a bad
hyperlipidemia or hyperglycemia control during the 8 years in the follow-up group. A “bad
hyperlipidemia or hyperglycemia control” is defined as persons with fasting serum TG ≥ 2.3 mmol/L, or TC ≥ 6.2 mmol/L, or GLU ≥ 7.0 mmol/L for ≥ 3 times among the total 8 examinations.

Statistical analysis

All the data of clinical samples were obtained from the laboratory information system (LIS). All statistical analyses were performed using the IBM SPSS 22.0 software program. However, serum lipids and glucose concentrations didn’t distribute normally and were expressed as the median (interquartile range). Differences between gender groups were assessed by 2 independent samples Mann-Whitney test. Differences among age groups were tested by Kruskal-Wallis test. Furthermore, differences of the prevalence of hyperlipidemia and hyperglycemia between the groups were assessed by the Poisson chi-square test. All p values were two-sided, and a p value < 0.05 was considered statistically significant.

Results

The levels of serum lipids and glucose in the control group

From 2012 to 2019, 5043 people have taken part in the health examination for 8 consecutive years. In the same period, 136,994 participants (the control group) had a health examination only 1 time. The number of participants in each age group was shown in Table 1. The age of all the participants ranged from 18 to 100.

The levels of serum lipids and glucose based on the data of control group from 2012 to 2019 were shown in Table 2. Serum TG increased with aging in both genders. For the male, serum TG was 1.05 mmol/L in ≤30 year group and a 1.42-fold increase was found in 41-50 year group (p < 0.001). After the age of 50, serum TG began to decrease slightly. Unlike the male, serum TG of female was 0.67 mmol/L in ≤30 year group and increased continuously after menopausal period. In 61-70 year group, it had a maximum value (1.30 mmol/L) and almost doubled (p < 0.001).

In consistence with serum TG, serum TC of male showed an obvious age-dependent increase and reached the highest level (4.95 mmol/L) in 51-60 year group. After that, it dropped slowly. In ≥71 year group, serum TC returned to the same value with the ≤30 year group. For the female, under the age of menopause, serum TC was lower compared with that of the age-matched male (p < 0.001). In 51-60 year group, it had a maximum value (5.34 mmol/L), even higher than the age-matched male. Despite serum TC of female decreased after menopausal period, it still exceeded the level of ≤30 year group far away (p < 0.001).
The change patterns of serum LDL-C in both genders were similar to the level of serum TC. Serum LDL-C peaked in 51-60 year group of both genders. After menopausal period, serum LDL-C of female decreased but it was always higher than the age-matched male \((p < 0.001)\). On the contrary, serum HDL-C decreased at first and then increased with aging, which was significantly different with TG, TC and LDL-C. In addition, serum HDL-C of male was always lower than that of the age-matched female. Serum GLU exhibited an age-dependent increase markedly in both genders. 1.16- and 1.17-fold higher levels for male and female were found in \(\geq 71\) year group compared with the \(\leq 30\) year group (both \(p < 0.001\)), respectively. Furthermore, during the whole life-span, serum GLU of female was always lower than that of the age-matched male, even after the age of menopause.

**Effect of annual health examination on the levels of serum TG, TC and GLU in the follow-up group**

Because the number of participants of \(\leq 30\) year group in the 8th year of the follow-up group was small (Table 1), to avoid introducing bias in calculating the levels and the incidence rate, we merged \(\leq 30\) year group and 31-40 year group to be \(\leq 40\) year group. The levels of serum TG, TC and GLU in 2019 of the control group, the 1st and 8th health examination year of the follow-up group were listed in Table 3. Firstly, we performed a cross-sectional comparison, comparing the levels of serum TG, TC and GLU between the 8th year of the follow-up group and 2019 of the control group. Our results established that compared with 2019 of the control group, serum TC and GLU in the 8th year of the follow-up group increased obviously in the \(\leq 40\) year group (all \(p < 0.001\)), which was present in both genders. Additionally, serum TC and GLU in the 8th year of the follow-up group were much higher than 2019 of the control group in the 41-50 year group (both \(p < 0.001\)), which was present only in female. Surprisingly, in the 61-70 year groups, serum GLU of female in the 8th year of the follow-up group was also higher than 2019 of the control group (\(p < 0.001\)). In the other age groups, there were no significant differences of serum TG, TC and GLU levels between the 8th year of the follow-up and the control group in 2019 (all \(p > 0.05\)).

Secondly, we compared the levels of serum TG, TC and GLU between the 1st and the 8th year of the follow-up group longitudinally. Our results showed that in the \(\leq 40\) year group, serum TG and TC of both genders in the 8th year significantly increased compared with those in the 1st year (all \(p < 0.001\)). Additionally, in the 41-50, 51-60 and 61-70 year groups, serum TC of female in the 8th year increased
markedly compared with those in the 1st year (all \( p < 0.001 \)). These results suggested that serum TC of female demonstrated a more obvious increase compared with the age-matched male from 2012 to 2019. On the whole, there were no significant differences of serum GLU levels between the 1st and the 8th year of the follow-up (all \( p > 0.05 \)).

The prevalence of hyperlipidemia and hyperglycemia in the control group

According to the diagnostic criteria, the incidence rates of hyperlipidemia in the control group from 2012 to 2019 were listed in Table 4.

Firstly, we investigated the relationship between the percentage of hyperlipidemia and age. The results showed that the prevalence of hyperlipidemia increased steadily with aging, no matter with the gender. For the male, the percentages of hyperlipidemia peaked in the 41-50y group. However, it had a maximum value for the female in the 61-70y group, which was consistent with the levels of serum TG. Secondly, we investigated whether the percentage of hyperlipidemia increased from 2012 to 2019 in each age group. Through the Trend chi-square test, we found that the percentages of hyperlipidemia of male didn’t exhibit a linear increase in all the age groups during the 8 years. However, the percentages of hyperlipidemia of female in the \( \leq 40 \), 41-50, 51-60 and 61-70 year groups increased steadily from 2012 to 2019 (Trend chi-squares 54.55, 7.45, 29.55 and 7.61, respectively, all \( p < 0.05 \)).

The incidence rates of hyperglycemia in the control group from 2012 to 2019 were listed in Table 5. The percentages of hyperglycemia also exhibited an age-dependent increase markedly in both genders. Similar to the levels of serum GLU, the percentages of hyperglycemia of male were always higher than those of the age-matched female. It should be noticed that the percentages of hyperglycemia of female increased more rapidly with aging than that of male. Such as, in 2013, the percentage of hyperglycemia of male was 4.91 folds as that of female in the \( \leq 40 \) year group; but, it was only 1.28 folds as that of female in the \( \geq 71 \) year group. Furthermore, through the Trend chi-square test, the prevalence of hyperglycemia of male increased steadily in the \( \leq 40 \) and 61-70 year groups from 2012 to 2019 (Trend chi-square 27.21 and 14.10, respectively, both \( p < 0.05 \)). And the percentages of hyperlipidemia of female didn’t show differences in all the age groups in the consecutive 8 years.

Effect of annual health examination on the prevalence of hyperlipidemia and hyperglycemia

The incidence rates of hyperlipidemia in 2019 of the control group, the 1st and 8th year of the
follow-up group were listed in Table 6. Compared with the non-consecutive group in 2019, there was
only a significant difference of the percentages of hyperlipidemia of female in the 8th year of the
follow-up group in the ≤40y group (p < 0.05). Compared with the 1st year, the incidence rates of
hyperlipidemia of both genders in the 8th year increased steadily in the ≤40 year group (both p < 0.05).
It should be noticed that, for the female under the age of 60, the percentages of hyperlipidemia in the
8th year were significantly higher than those in the 1st year of the follow-up group (all p < 0.05). These
were in accordance with the change pattern of serum TC in female of the follow-up group completely.
As a whole, the percentages of hyperlipidemia of female in the 8th year showed significant increase
compared with the 1st year of the follow-up group and 2019 of the control group (all p < 0.05). For the
male, there were no differences of the percentages of hyperlipidemia among these three groups.

The incidence rates of hyperglycemia in 2019 of the control group, the 1st and 8th year of the
follow-up group were listed in Table 7. Compared with the control group in 2019, there were
significant differences of the percentages of hyperglycemia of female in the 8th year in most of the age
groups (all p < 0.05), consistent with serum GLU of female. Additionally, compared with the 1st year,
the percentages of hyperglycemia in the 8th year increased significantly in the 61-70 and ≥71 year
groups for the male and in the 41-50 and 61-70 year groups for the female, respectively (all p < 0.05).
On the whole, the percentages of hyperglycemia in the 8th year showed significant increase compared
with the 1st year of the follow-up group and 2019 of the control group (all p < 0.05), which was present
in both genders.

Among the total 5043 participants, 2285 (45.31%) had been diagnosed as hyperlipidemia from 2012
to 2019. Of them, 1107(1107/2285, 48.45%) had been hyperlipidemia 1 or 2 times and 1168
(1168/2285, 51.12%) had a bad hyperlipidemia control (over 3 times). Additionally, of the 5043
participants, 752 (14.91%) had been diagnosed as hyperglycemia. Of them, 318 (318/752, 42.29%) had
been hyperglycemia 1 or 2 times and 434 (434/752, 57.71%) had a bad hyperglycemia control.

Discussion
Regular physical examination is recommended in China to protection and treatment of CVD and DM,
but its effectiveness in the control of hyperlipidemia and hyperglycemia has not been proved. So, we
firstly investigated the changing pattern of serum lipids and glucose in the general population with
aging. Since the concentrations of serum lipids and glucose in some groups didn’t distribute normally,
all the results were expressed as the median (interquartile range). It was found that serum TG of male exhibited the pattern of first increase, then decrease. serum TG of female showed an obvious increase with aging, similar to the report of Gan [12]. The change pattern of serum LDL-C was in accordance with serum TC in both genders, which peaked in 51-60y group and decreased after menopausal period. Serum HDL-C followed the pattern of first decrease and then increase with aging. Serum glucose in both genders demonstrated an age-dependent increasing pattern, consistent with the previous reports [13-14]. Our research further confirmed that the highest increase of serum lipids and glucose in women took place during the menopausal period. Therefore, annual health examination was also recommended for the female after menopausal period to prevent and treat the CVD and DM.

We evaluated the effectiveness of annual health examination to hyperlipidemia and hyperglycemia control through 3 approaches. After 8 years’ consecutive health examination, the levels of serum lipids and glucose in the follow-up group was not lower than those of the control group in 2019. Additionally, our results showed that serum TG and TC of the 8th year increased significantly compared with the 1st year of the follow-up group, which was consistent with the report of Gan [12]. However, we demonstrated that there was no significant difference of serum GLU between the 8th and the 1th year of the follow-up group, which was unlike with the result of Gan. In our study, serum GLU in the 1th year of the follow-up group were similar to those of the control groups in all the age groups, but serum GLU in the 1th year of the follow-up group were much lower than those in 2016 of the control groups in Gan [12].

All these results suggested that annual health examination didn’t reduce the levels of serum TG, TC and GLU and prevent the development of CVD and DM. Moreover, the percentages of hyperlipidemia and hyperglycemia in the 8th year showed significant increase compared with the 1st year of the follow-up group and 2019 of the control group (all \( p < 0.05 \)). Therefore, these results indicated that after 8 years’ consecutive health examination, annual health examination didn’t perform a positive effect in the prevention of hyperlipidemia and hyperglycemia.

With the development of economy, the prevalence of adult obesity and central obesity increased annually from 1997 to 2011 [15]. Then, the prevalence of dyslipidemia and diabetes have increased remarkably in China recently. In recent years, lines of evidence from epidemiological investigations, clinical and experimental research emerged showing that lifestyle management such as diet and exercise promoted the improvement of hyperlipidemia and hyperglycemia [16-18].
that regular aerobic exercise had beneficial effects on lipid levels, particularly if performed for at least 120 minutes per week in 2010 [19]. Li G et al. reported that a 6-year lifestyle intervention programme for Chinese people with impaired glucose tolerance could reduce incidence of cardiovascular and all-cause mortality and diabetes [20]. These findings further confirmed that the long-term of lifestyle intervention induced clinical benefits for patients with impaired glucose tolerance and lifestyle interventions should be as public health measures to control the consequences of diabetes. Therefore, American Diabetes Association established Lifestyle Management: Standards of Medical Care in Diabetes-2019 in 2019 [21].

It is widely known that the purpose of annual health examination is to find and treat the diseases as early as possible. Early or mild hyperlipidemia and hyperglycemia will not lead to any discomfort to the body. Once one patient is diagnosed as hyperlipidemia or hyperglycemia, diet control and lifestyle improvement have been the basic measures for the treatment of dyslipidemia and diabetes. However, for a health examination participant, compliance of diet control and lifestyle management was usually poor, which has become a common problem at present. Our results also indicated that more than half participants diagnosed as hyperlipidemia and hyperglycemia had a bad control. Consistent with our results, Lau et al. found that a general population to participate in a repeated screening and lifestyle counselling programme over five years did not result in lower incidence of diabetes after 10 years of follow-up [22]. So, it is necessary to perform a population-based education on health eating and physical activity. Health management should be paid more attention to prevent cardiovascular disease and diabetes.

Conclusions

In conclusion, our data showed that annual health examination didn’t show a positive effect in the prevention of hyperlipidemia and hyperglycemia. Health management should be paid more attention to prevent cardiovascular disease and diabetes.
