Reductions in nitrogen oxides over Europe driven by environmental policy and economic recession

Fuel combustion is a significant source of numerous air pollutants, which reduce local air quality, and affect global tropospheric chemistry. Satellite observations of nitrogen dioxide, emitted by combustion processes, allow for robust monitoring of atmospheric concentrations at high spatial resolution on continental scales. Here we evaluate changes in tropospheric NO2 concentrations over Europe between 2004 and 2010. We isolate long-term (timescales greater than one year) variability in the daily NO2 observations from the Ozone Monitoring Instrument (OMI) using a spectral analysis. In 2010, we find substantial reductions in NO2 concentrations of at least 20% throughout Europe. These reductions are as much the result of temporary reductions prompted by the 2008–2009 global economic recession, as of European NOx emission controls. Our results demonstrate that realistic concentration pathways of NO2 do not follow simple linear trends, but reflect a compilation of environmental policy and economic activity.

Nitrogen oxides (NOx = NO + NO2) play an important role in many atmospheric processes with strong implications for ecosystem stability, climate change, and public health. In polluted areas, NOx is produced in massive amounts by anthropogenic combustion primarily in the form of NO, which is rapidly transformed into NO2 by reaction with ozone. During the daytime, photolysis of NO2 leads to a steady state between NO and NO2 such that under typical urban conditions, at midday, roughly half of NOx is in the form of NO2. In the lower atmosphere, NOx contributes to acid deposition as well as ozone and aerosol formation. Moreover, at high concentrations NOx is toxic.

Accurate knowledge of changes in NOx concentrations is essential in order to monitor the effectiveness of air pollution abatement strategies in the context of changes in economic activity. Conventional methods to measure NOx used in surface observation networks can produce poorly quantified high biases. Surface sites are sparse, lack spatial representativity, and can be heavily influenced by nearby sources. Particularly over Europe, where NOx trends have been small over the last decade due to modest changes in emissions standards and economic growth compared to North America and east Asia, trends inferred from these networks may not represent the true changes in NOx concentrations. Indeed, trends in European NOx emissions and surface monitored NOx have been inconsistent.

Satellite observations of NO2 tropospheric columns have become increasingly useful for observing trends in NO2 concentrations and inferring surface NOx emissions from particular sources on regional and global scales. Satellite observations cover a large area and provide an impartial, self-consistent time series of NO2 concentrations. In the following we present trends in NO2 concentrations over Europe measured with the Ozone Monitoring Instrument (OMI) between October 2004 and December 2010 (see Methods). We use tropospheric NO2 columns observed under ‘cloud free’ conditions (cloud fraction below 20%) at 13:40 hours local time (DOMINO v1.02, see Methods). The high spatial resolution and sampling frequency of OMI observations (down to 24 km×13 km pixel size and daily global coverage) enable the detection of relatively small interannual variability within the NO2 signal. Here we isolate the low frequency (having periodicity greater than 1.4 years) components in the 2004–2010 NO2 time series by conducting a spectral analysis on the daily observations as discussed in the Methods and illustrated (for the case of Madrid) in Figure 1, thus avoiding the need to make assumptions about the seasonal variability of NO2 (e.g. Ref. 4 & 22), which could introduce errors in the estimate of the trend.

During the time period under consideration, the 2008–2009 global economic recession effectuated a distinct change in anthropogenic activity in Europe, indicated by sharp downturns in gross domestic product (GDP),
in addition to continuing NOx emissions reductions related to reductions in NO2 concentrations associated with the global economic recession. By the end of 2010, the reduction in NO2 concentrations intimates that some of the 2008–2009 changes in NO2 concentration are due to economic factors. The European Environment Agency (EEA)26, suggesting a linear trend that meteorological variability may have influenced apparent changes in tropospheric NO2. We find from regression modeling of the NO2 first derivative with several meteorological parameters that while taking into account meteorological trends and/or variability resulted in a better fit to the data between 2004 and 2008, it had negligible influence on the calculated terms (to within their 95% confidence intervals) over most of Europe (see Supplementary Information). The calculated total change in NO2 associated with environmental policy is shown in Figure 4(left). Table S1 presents specific values for cities with populations greater than 500,000, labeled with black diamonds in Figure 4 as well as values for the locations of three power stations indicated with green boxes. In Germany, Spain, southern France, Italy, Austria, Hungary, and parts of western Germany, eastern Germany along the Polish border (where the largest German coal-fired power plant is located), northwestern Spain (70% declines at the Compostilla II plant; green box in Figure 4), and the Po Valley, suggesting the installation of new NOx emissions controls and/or more efficient combustion technology. Fluxes in the low-pass filtered NO2 concentration suggest that meteorological variability may have influenced apparent changes in tropospheric NO2. We find from regression modeling of the NO2 first derivative with several meteorological parameters that while taking into account meteorological trends and/or variability resulted in a better fit to the data between 2004 and 2008, it had negligible influence on the calculated terms (to within their 95% confidence intervals) over most of Europe (see Supplementary Information).

The timing of the recession term is allowed to vary between grid cells in order to account for variability in local economies. We assume the rate of NO2 changes return to pre-2008 levels after the recession.

**Comparison of policy and recession driven NO2 changes.** Figure 3 shows the fitted and observed low-pass filtered NO2 concentrations averaged over the UK, Netherlands, Belgium, and northern France, the region of highest NO2 concentrations in Europe (area delineated by white box in Figure 2(top left)). During the estimated local recession time period (starting between June 2007 and October 2008 for that region), it is apparent that observed NO2 reductions are accelerating. By fitting the NO2 first derivative to Eqn. 1 we are able to reproduce the observed variability (Figure 3). If the small pre-recession trends in this region, as calculated from the regression fit, had continued through 2010, the reduction in NO2 concentrations would have been only 2–4% as opposed to the observed ~15%. Thus a large fraction of the improvements in air quality over northern Europe by 2010 are likely a result of NOx emissions reductions driven by episodic economic downturns.

Fluctuations in the low-pass filtered NO2 concentration suggest that meteorological variability may have influenced apparent changes in tropospheric NO2. We find from regression modeling of the NO2 first derivative with several meteorological parameters that while taking into account meteorological trends and/or variability resulted in a better fit to the data between 2004 and 2008, it had negligible influence on the calculated terms (to within their 95% confidence intervals) over most of Europe (see Supplementary Information). The calculated total change in NO2 associated with environmental policy (continuous×2283 days - the length of the 2004–2010 OMI observation time series used here) is shown in Figure 4(left). Table S1 presents specific values for cities with populations greater than 500,000, labeled with black diamonds in Figure 4 as well as values for the locations of three power stations indicated with green boxes. In Germany, Spain, southern France, Italy, Austria, Hungary, and parts of western Poland we find 10–50% reductions in NO2 concentration between 2004 and 2010. The strongest NO2 reductions occur in industrial areas where large power plants are located, such as southwestern Germany, eastern Germany along the Polish border (where the largest German coal-fired power plant is located), northwestern Spain (~70% declines at the Compostilla II plant; green box in Figure 4), and the Po Valley, suggesting the installation of new NOx emissions controls and/or more efficient combustion technology. Figure 4(left) also indicates increased NO2 (30–50%) around the largest cities in the UK, the English Channel, Ukraine, northeast Poland, and Turkey. Hot spots in Poland and Turkey correspond with construction of the Ostrołaka Mill power station starting in 2008 and the upgrade of the Hamitabat power station, respectively (green boxes in Figure 4). Increased NO2 concentrations in the areas surrounding London might be indicative of suburban development.

**Results**

Multi-year changes in tropospheric NO2 columns. Figure 2 shows August average low-pass filtered OMI tropospheric NO2 columns over Europe. NO2 concentrations in 2005 are particularly high in densely populated and industrial areas. The observations indicate that NO2 concentrations declined by up to 20% between 2005 and 2008 in many polluted regions (e.g. Germany, the Netherlands, Belgium, Italy, Spain), but increased by up to 15% over the North Sea and eastern Europe. In the year 2009, NO2 concentrations are at least 10% lower than 2005 values everywhere, but 20–40% lower than 2005 values in industrialized regions of Germany, the Po Valley, northwestern Spain, and large cities. This across the board reduction in NO2 coincides with the change in anthropogenic activity associated with the global economic recession. By the end of 2010, economic indicators for many European countries began to return to pre-recession levels. Reductions in NO2 concentrations generally slowed down in 2010, possibly indicating the beginning of economic recovery. Overall, NO2 concentrations at the end of 2010 are 20–30% lower than in 2005; with few exceptions, air quality over Europe has improved.

Environmental policy vs economic recession: regression modeling. Over Europe we expect that changes in NO2 columns respond proportionally to changes in NOx emissions. Although gradual reductions in NOx emissions over 2004–2009 have been reported to the European Environment Agency (EEA)25, suggesting a linear trend in NOx emissions and NO2 concentrations, the clear nonlinearity in the 2008–2009 changes in NO2 concentration intimates that some of the air quality improvements by the end of 2010 are independent of European environmental policy and may be associated with economic recession. Thus we attempt to separate the observed NO2 multi-year changes into recession and ‘business-as-usual’ components.

We fit the first derivative of low-pass filtered observed NO2 columns (d\(n_{\text{obs}} \)/dt) to Eqn. 1 (see Supplementary Information: ‘Regression Modeling’). We assume NO2 concentrations are changing at a constant rate (\(c_{\text{continuous}}\)) throughout 2004–2010 as a result of the competition between stable economic growth and continuing vehicle turnover and installation of control technology at point sources. For the period of economic recession, we implement an additional reduction (\(t_{\text{recession}}\)), which we assume lasts for one year and is centered on the minimum observed NO2 first derivative occurring after 2008 in each grid cell.

\[
\frac{dn_{103,6}}{dt} = \left\{ \begin{array}{ll}
\text{continuous} & \text{for } t \neq \text{recession} \\
\text{continuous} + \text{recession} & \text{for } t = \text{recession}
\end{array} \right.
\]

(1)

The calculated total change in NO2 associated with environmental policy (\(c_{\text{continuous}}\times2283 \text{ days} - \text{the length of the 2004–2010 OMI observation time series used here}\)) is shown in Figure 4(left). Table S1 presents specific values for cities with populations greater than 500,000, labeled with black diamonds in Figure 4 as well as values for the locations of three power stations indicated with green boxes. In Germany, Spain, southern France, Italy, Austria, Hungary, and parts of western Poland we find 10–50% reductions in NO2 concentration between 2004 and 2010. The strongest NO2 reductions occur in industrial areas where large power plants are located, such as southwestern Germany, eastern Germany along the Polish border (where the largest German coal-fired power plant is located), northwestern Spain (~70% declines at the Compostilla II plant; green box in Figure 4), and the Po Valley, suggesting the installation of new NOx emissions controls and/or more efficient combustion technology. Figure 4(left) also indicates increased NO2 (30–50%) around the largest cities in the UK, the English Channel, Ukraine, northeast Poland, and Turkey. Hot spots in Poland and Turkey correspond with construction of the Ostrołaka Mill power station starting in 2008 and the upgrade of the Hamitabat power station, respectively (green boxes in Figure 4). Increased NO2 concentrations in the areas surrounding London might be indicative of suburban development.
especially along the M11 highway corridor north of London), and increased motor vehicle traffic along the city’s periphery in response to the 2007 congestion tax discouraging driving in the city center.

At the national scale, for most European countries we find the calculated business-as-usual NO\textsubscript{2} changes are in line with trends in NO\textsubscript{x} emissions reported to the EEA for 2004 to 2007 (Figure S5). However, positive NO\textsubscript{2} trends over the UK are inconsistent with reported declining emissions, and the Netherlands, France, Czech Republic, and Belgium report stronger emissions reductions than suggested by the observed NO\textsubscript{2} trend.

Figure 4(right) shows 10–30% one-year recession-driven NO\textsubscript{2} reductions over most areas in Europe. The largest decreases in NO\textsubscript{2} associated with the recession occur over the southern North Sea and English Channel (an area of intense ship traffic), as well as the UK, Poland, southern Germany, France, and Turkey. Figure 5 shows the European average time series of NO\textsubscript{2} concentration with industrial production index (IPI) reported by the statistical office of the European Union (Eurostat). Industrial production index is an economic indicator for price-adjusted output of manufacturing, mining, and energy production. NO\textsubscript{2} concentrations decline between 2004 and 2008 in spite of economic growth, clearly indicating the effectiveness of environmental policy. The recession period decline in IPI is correlated with and proportional to observed NO\textsubscript{2} reductions at the national level, as illustrated by coincident 5–20% decreases in IPI and NO\textsubscript{2} concentration for all European countries (lower left quadrant of Figure 5(left)), further indicating the role of economic downturn in improving air quality across Europe. Scatter in the ratios of recession period NO\textsubscript{2} reduction to IPI in Figure 5 reflects country-to-country differences in (1) the ratio of NO\textsubscript{x} emissions from industrial sources to transportation, (2) the dominant type of industry (differing ratios of activity to emissions), and (3) progress in implementation of NO\textsubscript{x} emissions controls. Figures 3 and 5 show that as the European economy begins to recover, and industrial activity increases, NO\textsubscript{2} reductions are likely to slow down.

In Figure 6 we compare total NO\textsubscript{2} concentration changes before the recession to NO\textsubscript{2} concentration changes during the recession (see Figure S6 for all cities). With the exception of London, Birmingham, Paris, Minsk, Helsinki, Hamburg, and Mykolaiv, all of Europe’s largest cities underwent net decreases in NO\textsubscript{2} concentrations prior to the economic recession. Assuming that the ratio of a relative change in tropospheric NO\textsubscript{2} to a relative change in NO\textsubscript{x} emissions is approximately constant over 2004–2010 (Lamsal et al.\textsuperscript{25} report that this ratio varies by less than 3%), the change in NO\textsubscript{2} concentration during the recession divided by the business-as-usual change in NO\textsubscript{2} leading up to the recession is comparable to the ratio of NO\textsubscript{x} emissions changes during the two time periods. In general, reductions in

Figure 2 | August 2005 average low-pass filtered OMI tropospheric NO\textsubscript{2} columns ($n_{0,3,6}$) (top left), and the 2006–2010 August average low-pass filtered NO\textsubscript{2} columns normalized by August 2005 values. Grid cells are considered if less than 5% of the original data were invalidated and the resulting probability distribution does not differ significantly from the original data (Mann-Whitney U test, $p = 0.05$ one-tailed)(See Supplementary Information).
indicates that environmental policy measures drove 10–50% improvements over the course of 2004–2010. Our regression modeling

Discussion

With daily tropospheric NO\textsubscript{2} column observations from OMI, we are able to present spatially and temporally heterogeneous multi-year changes in NO\textsubscript{2}. Overall, air quality over Europe has improved over the course of 2004–2010. Our regression modeling indicates that environmental policy measures drove 10–50% declines in NO\textsubscript{2} over Europe between 2004 and 2010. That the largest NO\textsubscript{2} reductions occurred in industrialized areas (e.g. ~70% declines at the Compostilla II power station in northwest Spain) confirms implementation of NO\textsubscript{x} emissions controls obliged by policy measures. Areas where the calculated policy driven NO\textsubscript{2} change is positive correspond to regions that have seen significant economic development and associated increases in fuel combustion; for example, the construction of the Ostrelka Mill power station in northwestern Poland, and the upgrade of the Hamitabat power station northwest of Istanbul have led to net increases in NO\textsubscript{2} concentration (~5%) despite the recession. Notably, the UK has reported decreasing NO\textsubscript{x} emissions while NO\textsubscript{2} concentrations have increased mostly surrounding London, suggesting increased pollution as a result of suburban development or motor vehicle congestion.

In 2009, the global recession accelerated NO\textsubscript{2} reductions; European NO\textsubscript{2} concentrations decreased by 15–30% relative to 2004 concentrations as a result of fast declines in NO\textsubscript{x} emissions. Particularly, the shipping lane between the UK and continental Europe shows large decreases during the recession. The coastlines of the neighboring countries – Belgium, France, the Netherlands, and UK - follow the same trend. Modeling sensitivity studies focused on northern Europe show that emissions from ships may contribute about 10% to the surface NO\textsubscript{2} concentration over land in the Netherlands, Belgium, northern France, and southern UK\textsuperscript{27}. It is telling that these countries, whose emissions inventories are considered the most accurate in Europe, all show NO\textsubscript{2} trends that are smaller than would be implied by their reported NO\textsubscript{x} emissions reductions. While land based NO\textsubscript{x} emissions from internal combustion engines have been subject to legislation for over 20 years, emissions from shipping have gone largely uncontrolled. Thus the lack of emissions controls on shipping emissions in the channel may be suppressing air quality improvements for Belgium, France, Netherlands, and UK.

In many large cities across Europe, the NO\textsubscript{x} emissions reduction during roughly one year of economic downturn outweighed approximately 4 years of policy improvements. We found that rapid NO\textsubscript{2} reductions generally correlate well with sharp reductions in industrial activity over Europe. These findings are of relevance to demonstrating that realistic NO\textsubscript{x} emissions scenarios and NO\textsubscript{2} concentration pathways do not follow simple linear trends, but instead reflect a compilation of environmental policy measures and economic activity, at least over Europe.

Because satellites offer global coverage, our method to analyze the observation time series can be applied to any region, city, or major point source worldwide. The independent and up-to-date monitoring of changes in NO\textsubscript{2} concentrations that satellites provide will benefit from the continuation of ongoing observations and the improved spatial resolution from future (geostationary) satellite instruments.

Methods

Satellite Observations. We use NO\textsubscript{2} tropospheric vertical column densities from OMI\textsuperscript{19} retrieved with the Dutch OMI NO\textsubscript{2} algorithm (DOMINO) version 1.02 over Europe (37° N to 62° N and −9° W to 33° E). NO\textsubscript{2} tropospheric columns are derived with a three-step approach: (1) NO\textsubscript{2} slant columns are retrieved with Differential Optical Absorption Spectroscopy in the 405–465 nm wavelength range (spectral resolution of 0.5 nm), (2) OMI NO\textsubscript{2} slant columns are assimilated in the global chemistry transport model TM4\textsuperscript{28}, which provides the stratospheric background and a priori NO\textsubscript{2} profile shape needed to calculate the tropospheric air mass factor, which is used to (3) convert the tropospheric slant column into a vertical column\textsuperscript{24}. The OMI pixel size varies from 24 km × 13 km at nadir to 140 km × 26 km at the edges of the swath. Individual pixels, weighted by the cosine of the viewing zenith angle, were re-gridded to 0.125° latitude by 0.25° longitude (~14 km × ~20 km). Pixels affected by the row anomaly (tracks 27–44 and 53–54)\textsuperscript{39} were excluded for the entire 2004–2010 time period.

Isolating Multi-year Changes in NO\textsubscript{2}. The KZ Filter. To separate the NO\textsubscript{2} time series into different frequency components, we use the Kolmogorov-Zurbenko (KZ) filter\textsuperscript{40}. A KZ filter is simply k iterations of a successive moving average of window length (m).
where \( n_{m,k}(t) \) becomes the input for the second iteration of the filter, and so on. The transfer function of such a filter with \( k \geq 3 \) is essentially a step function that when applied on a linear system (e.g. the signal can be modeled as the sum of signals containing different frequency components) passes frequencies below a specified value (referred to as the separating frequency). The effective separating frequency (\( p \)) is approximately equal to \( \frac{1}{2} \). Thus, by choosing an appropriate \( k \) and \( m \), one can remove specific high frequency variations from data.

In this work, we examine the multi-year variability of NO2 that is a result of applying a KZ filter of 6 iterations of a 103-day moving average \((n_{103,6})\) to log-transformed (see Supplementary Information) daily data in each grid cell. This removes variations with periodicity less than approximately 1.4 years from the original signal. We choose 1.4 years as our effective separating frequency to minimize convolution of seasonal variability with long-term variability, which can occur if the effective filter width overlaps with frequencies close to one year. The effectiveness of the separation is tested by the covariance of filtered data and its’ residual \((r=n-n_{103,6})\). For our dataset, this is generally less than 3% of the total variance in the original signal (Figure S2). Thus, with seasonality effectively removed, variability in the filtered signal is driven by multi-year (here defined as time-scales greater than 1.4 years) changes in emissions and/or meteorology.

In Figure 3(top) we show observed monthly average concentrations and their 12-month running mean averaged over the eastern United Kingdom, Belgium, Luxembourg, and the Netherlands (see white box in Figure 2(top left)). We have also overlaid the corresponding average KZ-filtered signal. The absolute value of the KZ-filtered signal is offset because, as discussed in Supporting Information - “Spectral Analysis: Log Transformation”, the product of the long-term and higher variability signals reproduces the total signal. The KZ-filtered signal and 12-month running mean follow a similar pattern overall; there is an indication of a downward trend in NO2 concentration in both curves, but year-to-year changes are more difficult to discern from the 12-month running mean. NO2 concentrations in this part of northern Europe lack deterministic variability such as seasonality. The main driver of NO2 fluctuations is high frequency synoptic variability (timescales less than 3 months), which is apparent in the monthly
average data and is retained in the 12-month running mean. In contrast, for the case of Madrid (Figure 1), the seasonal cycle is the dominant mode of variability, and year-to-year changes are readily apparent. Thus, in order to discern long-term trends at high resolution over a large area like Europe, where the timescale of the mode of largest variability differs from region to region, we must use a time-series separation technique such as the KZ filter.

Figure 6 | The calculated total relative change in NO2 concentration before and during the economic recession for 18 large European cities with more than 500,000 inhabitants. Black bars indicate the total relative change in NO2 between 2004 and the estimated start of the economic recession (the business-as-usual time period where economic growth is offset by environmental policy). Grey bars indicate the change in NO2 during the yearlong economic recession (also relative to 2004). The average value is for all European cities with populations greater than 500,000 (see Figure S6). The areas considered for each city correspond to the average of the closest co-located grid cell and the surrounding 8 grid cells. The mid-date of the economic recession (inset city names) was estimated as the date with the observed highest rate of NO2 column decrease (minimum NO2 first derivative with respect to time) after 2008.
