Abstract  
We study the possibility of using W pair production and leptonic decay of one of the W’s at the ILC with polarized beams as a probe of the Littlest Higgs Model. We consider cross-sections, polarization fractions of the W’s, leptonic decay energy and angular distributions, and left-right polarization asymmetry as probes of the model. With parameter values allowed by present experimental constraints detectable effects on these observables at typical ILC energies of 500 GeV and 800 GeV will be present. Beam polarization is further found to enhance the sensitivity.

1 Introduction

One of the important processes that will be studied at high precision at ILC with and without beam polarization is W-pair production. Phenomenological studies of this process within the Standard Model (SM) have been carried out in great detail [1,2]. Since properties of the weak gauge bosons are closely linked to electroweak symmetry breaking (EWSB) and the structure of the gauge sector in general, detailed study of W physics will throw light on what lies beyond the SM. The study of mechanisms of EWSB is one of the main concerns of particle physics today. The standard Higgs mechanism is less than satisfactory, and faces difficulties such as the hierarchy problem. Looking beyond the SM, the newly proposed Little Higgs scenarios [3,4] provide a dynamical way to generate the EWSB, in contrast to the ad hoc introduction of the elementary scalar sector. Apart from this aesthetically appealing feature, Little Higgs models provides rich phenomenology with predictions that could be vindicated or ruled out at future colliders such as the LHC and the ILC.

One major feature of such models is the presence of additional gauge bosons in the physical spectrum. These influence processes like W-pair production in $e^+e^-$ collisions, firstly directly through their exchange in the process, and
secondly through the change of standard couplings through mixing with other
gauge bosons. Although these additional gauge bosons are typically too heavy
to be produced at reference ILC energies of 500 and 800 GeV which we use in
the present study, their effects manifest themselves as stated above. Recently
it was pointed out, in a preliminary study, that for one such model known as
the Littlest Higgs Model (LHM), the fraction of longitudinally and transversely
polarized of one of the W’s could be significantly different from the corresponding
fraction in the SM [5]. In this work, we consider a refined treatment of the
LHM to be described below, and extend the prior work to polarization fractions
and total cross-sections of the W’s, energy and angular distributions of decay
leptons, as well as to observables like the forward-backward and left-right asym-
metries, which are more sensitive to the effects of the LHM compared to the
cross-sections.

The ILC is expected to have large beam polarizations which will significantly
enhance the sensitivity to new physics, for a review, see ref. [6]. We consider
different beam polarizations with the aim of improving the sensitivity of the
observables considered here.

This article is organized as follows: in Section 2 we, very briefly, introduce
the LHM, and describe its particle spectrum and couplings relevant to \(e^+e^- \rightarrow
W^+W^-\). In Section 3 we present our analysis of the total cross section and W-
polarization fractions in the LHM and compare with the SM case. In Section 4
we take up the task of probing the model by considering decay of one of the W’s
to a lepton pair. We consider the energy and angular distributions for the cases
of SM and LHM. We also discuss the left-right as well as forward-backward
asymmetry in this section. Finally we summarize our study and present our
conclusions in Section 5. Note that we have included beam polarization effects
in this study in each of the relevant sections.

2 The Littlest Higgs Model and W Pair Production at ILC

In Little Higgs models [3] a non-linear realization of some global symmetry
\(G\) broken down to \(H\) is considered. The Nambu-Goldstone Bosons (NGB)
of the symmetry breaking are candidate Higgs fields. In a specific model,
called LHM [4] \(G \equiv SU(5)\) is broken down to \(H \equiv SO(5)\) via a vacuum ex-
pectation value (vev) of order \(f\). Interactions of NGB’s are described by a
non-linear sigma model, which is an effective theory valid below the cut off
\(\Lambda \sim 4\pi f\). In the version of the LHM [4, 7] we will consider in this report,
\(SU_1(2) \times SU_2(2) \times U_Y(1) \subset SU(5)\) is gauged, which is broken down to the SM
gauge group \(SU(2)_L \times U(1)_Y\). Under this, the 14 NGB’s transform as a real
singlet, a real triplet, a complex doublet and a complex triplet. The real fields
become the longitudinal degrees of the heavy gauge bosons, while the SM gauge
bosons, \(W^\mu_L\) and \(B^\mu_L\) remain massless at this stage. The doublet NGB field has
the correct quantum numbers to be identified as the standard Higgs doublet.

At
tree level, they have only derivative couplings, but quantum corrections at one-loop level generate a Coleman-Weinberg potential with quadratic and quartic terms, consequently breaking electroweak symmetry. Gauge symmetry is constructed such that, in the absence of any one (original) gauge interaction the Higgs is massless to all orders. This also ensures that quadratically divergent contributions to the mass-square term at one-loop level are cancelled between the gauge bosons from the two sectors. Logarithmically divergent terms contribute to the potential. In order to avoid a quadratic divergence due to a top-quark loop, a pair of (weak-singlet) Weyl quarks $U_L, U_R$ is introduced, which mix with the ordinary left- and right- quarks to give mass eigenstates. Here again, it is so arranged such that the quadratic divergence coming from the standard top-quark is cancelled by its heavy counterpart, and the logarithmically divergent part is added to the Coleman-Weinberg potential. The model achieves EWSB, at the same time, protecting the Higgs mass from acquiring quadratically divergent corrections at one loop. It is therefore to be expected that these models will have a rich phenomenology with distinct signatures that can be probed at upcoming collider experiments. An incomplete list of phenomenological studies of different variations of the Little Higgs Model scenarios is ref. \cite{9, 10, 8, 11}.

Our interest here is the effective theory below the cut-off $\Lambda$. For the process $e^+e^- \to W^+W^-$, we have an $s$-channel process with the exchange of the heavy neutral gauge boson, $Z_H$, in addition to the standard channels as shown in Fig.1.

\begin{figure}[h]
\centering
\includegraphics[width=\textwidth]{fig1.png}
\caption{Feynman diagrams contributing to the process $e^-e^+ \to W^+W^-$ in the LHM.}
\end{figure}

Apart from the contribution due to the additional $s$-channel process, the LHM also changes the SM couplings. The relevant couplings in terms of the parameters of the LHM is given below in terms of the global symmetry breaking scale $f$, the parameter $\cos \theta$, which represents mixing between the two gauge sectors of the LHM and the vev.

The three-point gauge couplings involving $WW$ are given by:

$$V^\mu(k_1)W^\nu(k_2)W^\rho(k_3) = ig_{VWW} \left[ g^{\mu\nu}(k_1 - k_2)^\rho + g^{\mu\rho}(k_2 - k_3)^\nu + g^{\mu\rho}(k_3 - k_1)^\nu \right],$$

where all the momenta are considered outflowing, and $V \equiv \gamma, Z, Z_H$. Individual $g_{VWW}$ are given by:
Fermion couplings are given by:

\[ g_{\nu W} = i g_{\gamma} \gamma_{\mu} \left( 1 - \frac{v^2}{2 f^2} \cos^2 \theta \cos 2\theta + \left( \frac{v^2}{2 f^2} \right) \gamma^5 \right) \]  

\[ g_{eeV} = i \gamma_{\mu} \left( c_v^\alpha - c_v^\gamma \gamma^5 \right), \]  

where

\[ c_v^\gamma = -e; \quad c_v^\alpha = 0 \]  

\[ c_Z^\gamma = -\frac{e}{\sin 2\theta_W} \left[ \left( \frac{1}{2} + 2 \sin^2 \theta_W \right) - \frac{v^2 \sin 4\theta \cot \theta}{f^2} \right] \]  

\[ c_Z^\alpha = -\frac{e}{\sin 2\theta_W} \left[ \frac{1}{2} - \frac{v^2 \sin 4\theta \cot \theta}{f^2} \right] \]  

\[ c_{ZH}^\gamma = c_{ZH}^\alpha = -\left( \frac{e \cot \theta}{4 \sin \theta_W} \right) \]  

Following ref. [10] we consider the measured values of the Fermi coupling constant, \( G_F \), the Z-boson mass, \( M_Z \), and the fine structure constant, \( \alpha_{em}(M_Z^2) \) as the Standard Model input parameters. The weak mixing angle is obtained from the relation:

\[ \sin^2 \theta_W \cos^2 \theta_W = \frac{\pi \alpha_{em}(M_Z^2)}{\sqrt{2} G_F M_Z^2}. \]

The bare weak mixing angle, \( \theta_W \), is related to the measured weak coupling angle, \( \theta_0 \), through the following relation:

\[ \cos \theta_W = \cos \theta_0 \left[ 1 + \frac{\sin^2 \theta_0}{\cos^2 \theta_0 - \sin^2 \theta_0} \left( \frac{v^2 \cos^2 \theta \sin^2 \theta}{2 f^2} + 2 \frac{|v'|^2}{v^2} \right) \right] \]

The weak coupling constant expressed in terms of the other parameters becomes

\[ g = \frac{2 m_W}{v} \left[ 1 + \frac{v^2}{2 f^2} \left( \frac{1}{6} + \frac{(\cos^2 \theta - \sin^2 \theta)^2}{4} \right) - 2 \frac{|v'|^2}{v^2} \right]. \]

The triplet vev, \( v' \), is related to the generated quartic coupling, and the gauge couplings through

\[ \frac{|v'|^2}{v^2} = \frac{v^2}{144 f^2} \left( 1 + \frac{6 \lambda - 4 a g_1^2}{a(2g^2 + g_1^2)} \right)^2, \]
which is further constrained to $|v'|^2/v^2 < v^2/16 f^2$ \cite{8}. In our numerical analysis we consider the approximate relation, $|v'|^2/v^2 = v^2/144 f^2$. Note that our numerical results are not very sensitive to this choice. Thus we are left with two free parameters $f$ and $\theta$. As argued by \cite{11}, precision electroweak measurements restrict the parameters to be $f \sim 1$ TeV and $0.1 < \cos \theta < 0.9$. In our numerical analysis we consider some representative values satisfying these restrictions.

3 Analyses of $e^- e^+ \to W^+ W^-$

In this section we present the results of our numerical analysis to probe the LHM through the process $e^- e^+ \to W^+ W^-$ at the ILC.

3.1 The total cross section

We compute the total cross section incorporating beam polarization using the helicity amplitudes given in ref. \cite{1} with the new couplings and with the added contribution due to the exchange of $Z_H$. With beam polarization, in general, the polarized cross section may be expressed as \cite{12}:

$$\sigma(e^+e^- \to W^+W^-) = \frac{1}{4} \left[ (1 + P_{e^-})(1 - P_{e^+})\sigma^{RL} + (1 - P_{e^-})(1 + P_{e^+})\sigma^{LR} \right],$$

where $\sigma^{RL} = \sigma(e^+_L e^-_R \to W^+W^-)$ and $\sigma^{LR} = \sigma(e^+_R e^-_L \to W^+W^-)$, with $e_{L,R}$ representing the left- and right-polarized electrons (and positrons), respectively. The degree of polarization is defined as: $P_e = (N_R - N_L)/(N_R + N_L)$, where $N_{L,R}$ denote the number of left-polarized and right-polarized electrons (and positrons), respectively. More than 80% of electron beam polarization and large positron beam polarization are expected to be achieved at ILC. In our analysis we consider the ideal possibility of 100% polarization of the beams. Our results are presented in the figures below.

In Fig. 2 we present the total production cross-section for a typical choice of parameters of the LHM and in the SM of the case of unpolarized and polarized beams with a specific choice of beam polarization. It may be seen that in the case of unpolarized beams the cross section of LHM does not deviate much from that of the SM for energies up to 1 TeV.

The presence of beam polarization changes this situation significantly. The combination, $P_{e^-} = +1$ and $P_{e^+} = 0$ is seen to provide the largest deviation, which is the case we have chosen to display. However, for this configuration a reduced number of $W$-pairs is produced, as the dominant $t$-channel is cut off. Notice also that there is no contribution due to the $Z_H$ exchange in this case, as the $Z_H$ couples only to the left-handed electrons. The effect, therefore, is purely due to the deviation of the standard model couplings. We will return to some more properties of this in the next sub-section.
Figure 2: Total cross section for $W^+ W^-$ production in an $e^+ e^-$ collision for SM [blue-solid] and LHM [red-dashed] with [a] unpolarized beams [b] polarized beams with $P_{e^-} = 1$ and $P_{e^+} = 0$. The parameters for LHM are $f = 1$ TeV and $c = 0.3$

3.2 \( W \) Polarization Fractions

Here we explore the sensitivity of the ILC to the LHM when we consider polarization fractions of the \( W \) bosons. Such measurements have been considered in past experiments for precision studies of the \( W \) boson properties at LEP, which has measured the fractional cross section of the polarized \( W \)'s [13]. At ILC higher precision is expected to be reached. We define the polarization fractions as

\[
\begin{align*}
    f^L &\equiv \frac{\sigma(e^+ e^- \to W^+_L W^-)}{\sigma_{\text{unpol}}} \\
    f^T &\equiv \frac{\sigma(e^+ e^- \to W^+_T W^-)}{\sigma_{\text{unpol}}},
\end{align*}
\]

where \( L \) stands for longitudinal polarization, and \( T = \pm \) stands for transverse polarizations.

The three polarization fractions are studied as a function of \( \sqrt{s} \) which are plotted in Fig. 3. It is readily observed that there is a significant deviation in the case of \( f^L \) and \( f^- \), while \( f^T \) is largely unaffected. Since these fractions depend on various couplings in a complicated way, we do not attempt to explain the effects in terms of the changes in the couplings.

In Table 1 we present firstly the ratio of the cross section in the LHM to that in the SM for typical parameter choices, as well as the ratio of \( f^0 \) in LHM to that in the SM at \( \sqrt{s} = 500 \) GeV and 800 GeV for the two illustrative parameter space points. At \( \sqrt{s} = 500 \) GeV for \( f = 1 \) TeV and \( c = 0.3 \) the deviation is about 65% with unpolarized beams. This is improved marginally to about 66% for \( P_{e^-} = -1, \ P_{e^+} = 0 \). While for the slightly larger value of, \( f = 1.5 \) TeV, the effect is not as dramatic, we still have significant deviation of about 25 - 30% in \( f^0 \). On the other hand, the configuration with purely right handed
electrons and unpolarized positrons has the effect of completely washing out the effect of the LHM in the polarization fractions. Therefore, beam polarization has the dramatic effect of disentangling the effects of the new physics. Crucially, there is an interplay between the pure left-handed coupling nature of $Z_H$ and the corrections to the couplings of the SM $Z$-boson coming from the parameters of the LHM which makes this possible. Considering the precision at which $f^0$ could be measured at ILC, such effects are very interesting.

![Fractional cross section of $W^-$, [a] longitudinal ($f^0$), and [b] transverse ($f^\pm$), with unpolarised beams for SM [blue - solid] and LHM [red - dashed]. The parameters in this case are $f=1$ TeV and $c=0.3$](image)

**3.3 Angular Spectrum of the Secondary Lepton**

In order to exploit further the process at hand, it is profitable to consider the decays of one or both the $W$'s. Let us consider $e^+e^- \rightarrow W^+W^-$ with $W^- \rightarrow l^-\bar{\nu}$ and $W^+$ going into anything. Energy-angle correlation of the secondary leptons is given by the following expression [14, 15]:

$$
\frac{d\sigma}{dx \; d\cos\theta_l} = \frac{3\alpha^2}{2} \frac{s}{\sqrt{s}} \text{BR}(W^- \rightarrow e^-\bar{\nu}) \; A(s, x, \theta_l) \times \left[ \arctan\left(\frac{m_W}{\Gamma_W}\right) + \arctan\left(\frac{sx}{m_W\Gamma_W} - \frac{s\tau}{m_W\Gamma_W(1-x)}\right) \right].
$$

(13)

Expression for the function $A(s, x, \theta_l)$ is given in the Appendix for arbitrary beam polarization, while in the above $x = 2E_l/\sqrt{s}$, where $E_l$ is the energy of the secondary lepton in the $e^+e^-$ centre of mass frame with $\sqrt{s}$ the centre of mass energy, and $\theta_l$ is its polar angle. $\text{BR}(W^- \rightarrow e^-\bar{\nu})$ is the leptonic branching ratio of $W$, $\Gamma_W$ is its width, and $\tau = m_W^2/s$. In principle, the decay width and
branching ratios of \( W \) can be different from those of the SM values. But, in the case when the additional fermions are heavy, we can assume an SM like decay of the \( W \). In our analysis we have taken this approach.

From the above energy-angle correlation, we obtain the \( \cos \theta \) distribution by numerically integrating over \( x \). Fig.4 shows the angular distribution for different polarization combinations for \( \sqrt{s} = 800 \) GeV. It may be noted that the \( \theta \) distribution closely follow the pattern of the angular distribution of the \( W \), which is expected to peak in the forward region for unpolarized beams and with left-polarized electron beams, but is symmetric in the case of right-polarized electron beams. This is expected as the \( W \) is produced with large kinetic energy, and the decay leptons are expected to follow its momentum direction. The case of right-handed electron beam Fig.4(c) is interesting. Recall that \( Z_H \) couples only to the left-handed electrons. Therefore, there is no contribution from the \( Z_H \) exchange when we have right-polarized electron beam. But, we still notice appreciable deviation in the angular distribution compared to the SM case. This comes about through the change in the SM couplings. Similar effect was seen in the case of total cross section also. In the case of \( \sqrt{s} = 500 \) GeV the effect is similar, but somewhat less pronounced and therefore not displayed here explicitly.

A useful quantity to obtain in the case of unpolarized and left-polarized beams is the fraction of leptons emitted in the backward direction, which may be defined as:

\[
f_{\text{back}} = \frac{\int_{-1}^{0} (d\sigma / d \cos \theta_l) \ d \cos \theta_l}{\int_{-1}^{1} (d\sigma / d \cos \theta_l) \ d \cos \theta_l}
\]
In Table 2 we present these fractions for $\sqrt{s} = 500$ GeV, and 800 GeV. The deviation is about 34% at $\sqrt{s} = 500$ GeV for $f=1$ TeV and $c=0.3$ with unpolarised beams. Notice that the effect is not very sensitive to the choice of $c$. But larger $f$ values tend to reduce the effect drastically. Using left-polarized electron beam ($P_{e^-} = -1$) does not affect the above results significantly. At $\sqrt{s} = 800$ GeV, the effects are even more dramatic, as can be judged from the Table. In the case of right-polarized electron beam ($P_{e^-} = +1$), $f_{\text{back}}$ remains the same in both LHM as well as SM.

![Figure 4: Angular distribution of secondary leptons at $\sqrt{s} = 800$ GeV within SM [blue - solid] and LHM with $f=1$ TeV, $c=0.3$ [red - dashed] and with $f=1.5$ TeV, $c=0.3$ [black - dot-dashed] for [a] unpolarized beams, [b] with $P_{e^-} = -1$ and $P_{e^+} = 0$, and [c] with $P_{e^-} = 1$ and $P_{e^+} = 0$](image)

Another useful observable related to the angular asymmetry is the forward-
\( s = 500 \text{GeV} \)
\( s = 800 \text{GeV} \)

\[ P_{e^{-}} \quad P_{e^{+}} \quad \text{Model} \quad f \text{ (TeV)} \quad c \quad \sqrt{s} = 500 \text{GeV} \quad \sqrt{s} = 800 \text{GeV} \]

| \( P_{e^{-}} \) | \( P_{e^{+}} \) | \( f \) (TeV) | \( c \) | \( A_{FB} \) | \( A_{FB} \) |
|-------------|-------------|-----------|-----|----------|----------|
| 0           | 0           | SM        | 1   | 0.3      | -0.94    | 0.024    | -0.95    |
| 0           | 0           | LHM       | 1.5 | 0.3      | -0.92    | 0.034    | -0.93    |
| 0           | 0           | LHM       | 1.5 | 0.5      | -0.92    | 0.032    | -0.94    |
| -1          | 0           | SM        | 1   | 0.3      | -0.94    | 0.022    | -0.96    |
| -1          | 0           | LHM       | 1.5 | 0.3      | -0.93    | 0.032    | -0.94    |
| -1          | 0           | LHM       | 1.5 | 0.5      | -0.93    | 0.030    | -0.94    |

Table 2: Fraction of leptons emitted in the backward direction, and the forward-backward asymmetry for both LHM and SM model for unpolarized and polarized beams with different choices of parameters.

The backward asymmetry defined as:

\[ A_{FB} = \frac{\int_{-1}^{0} (d\sigma / d\cos\theta_{l}) \ d\cos\theta_{l} - \int_{0}^{1} (d\sigma / d\cos\theta_{l}) \ d\cos\theta_{l}}{\int_{-1}^{1} (d\sigma / d\cos\theta_{l}) \ d\cos\theta_{l}}. \quad (14) \]

In Table 2 \( A_{FB} \) is tabulated for different parameter values at two different collider energies. Deviation of about 5% is observed in the asymmetry for \( f = 1 \ \text{TeV} \) and \( c = 0.3 \).

### 3.4 Energy Spectrum of the Secondary Lepton

The energy spectrum of the secondary leptons are sensitive to the \( W^{\pm} \) helicities. The energy distribution in the centre of mass frame may be written in terms of the polarization fractions of the \( W \)’s in the following form \[15\]:

\[ \frac{1}{\sigma} d\sigma dx = \frac{2}{\beta^{3}} \left[ \frac{3}{4} f^{0} (\beta^{2} - (1 - 2x)^{2}) + \frac{3}{8} f^{+} (\beta - 1 + 2x)^{2} + \frac{3}{8} f^{-} (\beta + 1 - 2x)^{2} \right]. \quad (15) \]

In Fig. 5 we present the energy spectrum of the charged decay lepton for \( \sqrt{s} = 800 \ \text{GeV} \). We notice that a slightly larger fraction of hard leptons are produced in the case of LHM compared to the case of the SM. The effect is much smaller in the case of \( \sqrt{s} = 500 \ \text{GeV} \). While it is true that the effect is not dramatic, given the fact that the lepton energy spectrum could be obtained...
easily and with high efficiency, this observable might be useful in probing the LHM.

Figure 5: The energy spectrum of the charged decay lepton in $e^+e^- \rightarrow W^+W^-$, with $W^- \rightarrow l^-\bar{\nu}$ at $\sqrt{s}=800$ GeV. Unpolarised beams are used for SM [blue - solid] and LHM [red - dashed]. The parameters in this case are $f=1$ TeV and $c=0.3$.

3.5 Left-Right Asymmetry

The new gauge boson $Z_H$ in the LHM has the peculiar property of coupling only to left handed fermions as mentioned earlier. On the other hand, the SM $Z$ couples to both left- and right-handed fermions, but the corrections to the $Ze^+e^-$ coupling is such that only the left-handed electron coupling is affected. Thus, one would expect appreciable change in the asymmetry between the left- and right-polarized cross section.

We define the left-right asymmetry in the differential cross section as:

$$A_{LR}^{diff} = \frac{d\sigma(e^-_Le^+_R \rightarrow W^+W^-)/d\cos\theta - d\sigma(e^-_Re^+_L \rightarrow W^+W^-)/d\cos\theta)}{d\sigma(e^-_Le^+_R \rightarrow W^+W^-)/d\cos\theta + d\sigma(e^-_Re^+_L \rightarrow W^+W^-)/d\cos\theta)},$$

where $\theta$ is the $W$ scattering angle. Fig. 6 shows the LR asymmetry for two energies. Even at low energies the deviation becomes apparent.

We may go one step further by considering an integral version of this asymmetry as better efficiency may be obtained this way, by integrating each of the differential cross sections from an opening angle $\theta_0$ up to an angle $\pi-\theta_0$, for various realistic values of $\theta_0$ to which the data can be integrated without difficulty.

We define the integrated left-right asymmetry as:

$$A_{LR} = \frac{\sigma_0(e^-_Le^+_R \rightarrow W^+W^-) - \sigma_0(e^-_Re^+_L \rightarrow W^+W^-)}{\sigma_0(e^-_Le^+_R \rightarrow W^+W^-) + \sigma_0(e^-_Re^+_L \rightarrow W^+W^-)},$$

where $\sigma_0$ stands for $\int_{\theta_0}^{\pi-\theta_0} (d\theta/d\theta)$. This asymmetry, for different parameter values at $\sqrt{s}=500$ GeV and at $\sqrt{s}=800$ GeV is tabulated in Table 3. We see that the asymmetry is not affected in any significant way at $\sqrt{s}=500$ GeV.
\[
\begin{array}{|c|c|c|c|}
\hline
\text{Model} & f \text{ (TeV)} & c & \sqrt{s} = 500 \text{GeV} & \sqrt{s} = 800 \text{GeV} \\
\hline
\theta_0 = 0 & & & & \\
\text{SM} & 1 & 0.3 & 0.988 & 0.986 \\
\text{LHM} & 1.5 & 0.3 & 0.990 & 0.992 \\
& 1.5 & 0.5 & 0.991 & 0.993 \\
\hline
\theta_0 = 15^\circ & & & & \\
\text{SM} & 1 & 0.3 & 0.978 & 0.967 \\
\text{LHM} & 1.5 & 0.3 & 0.982 & 0.979 \\
& 1.5 & 0.5 & 0.983 & 0.981 \\
\hline
\theta_0 = 30^\circ & & & & \\
\text{SM} & 1 & 0.3 & 0.962 & 0.945 \\
\text{LHM} & 1.5 & 0.3 & 0.969 & 0.964 \\
& 1.5 & 0.5 & 0.970 & 0.967 \\
\hline
\theta_0 = 45^\circ & & & & \\
\text{SM} & 1 & 0.3 & 0.945 & 0.920 \\
\text{LHM} & 1.5 & 0.3 & 0.953 & 0.945 \\
& 1.5 & 0.5 & 0.955 & 0.949 \\
\hline
\theta_0 = 60^\circ & & & & \\
\text{SM} & 1 & 0.3 & 0.927 & 0.897 \\
\text{LHM} & 1.5 & 0.3 & 0.937 & 0.926 \\
& 1.5 & 0.5 & 0.939 & 0.931 \\
\hline
\end{array}
\]

Table 3: \( A_{LR} \) for various opening angles \( \theta_0 \) for SM and LHM with different choice of parameters.
or at $\sqrt{s} = 800$ GeV for the parameter combinations considered, when no cut on angle is applied. Interesting patterns may be observed from this table. An interplay between the differential asymmetry plotted above, and the fact that the bulk of the contribution to the cross section comes from the forward region where the asymmetry itself is not appreciable leads to more significant results when the cut-off angle is larger. In other words, as the cut-off angle increases, the region of deviation between the LHM and the SM is weighted more efficiently. The case of $\theta = 15^\circ$ is worthy of note, as there is a cross-over in the asymmetry for $\sqrt{s} = 800$ GeV and the effect is completely wiped out.

4 Conclusions

Understanding the phenomenon of electroweak symmetry breaking is central to the study of elementary particle physics. Among the viable alternatives to the Standard Higgs Mechanism is the Little Higgs Scenarios, which provides a natural way to dynamically generate electroweak symmetry breaking. In this report we have considered the LHM which is one simple version of this scenario. Such a model predicts the existence of additional gauge bosons with masses in the TeV region. We have considered the process $e^+e^- \rightarrow W^+W^-$ to probe this model. Presence of a heavy neutral gauge boson in addition to the SM gauge bosons, and the change of couplings of the SM particles affect this process.

We have studied the total cross section and the polarization fraction of the $W$’s produced for typical parameter values. We conclude that for suitable choice of beam polarizations, there can be more than 50% deviation in the cross section for $\sqrt{s}$ around and above 500 GeV. The polarization fractions are found to be more sensitive to the new effects, which can be two or three times the SM value at $\sqrt{s} = 800$ GeV. The fact that the $W$ polarization fractions can be very precisely measured at ILC shows that study of these observables can effectively
probe the LHM.

Study of secondary lepton distributions can be carried out efficiently at the ILC. Our study of the energy and angular distributions in the laboratory frame shows that significant deviation from the SM expectation is possible for parameter sets of LHM allowed by the present experimental constraints. We see that the angular distribution is better suited in the present case with fraction of secondary leptons emitted in the backward direction deviates from the SM value by significant amounts. We have introduced a LR asymmetry for the differential as well as the integrated cases, where the integration is performed over an opening angle given by $\theta_0$. It is shown that a judicious choice of $\theta_0$ can provide a window for observing striking deviations from the SM and provide a discriminating tool for the LHM.

While a more complete study including, for instance, detector efficiencies, and larger parameter space scan is pending, our study with representative parameter points illustrates that $W$ pair production in $e^+e^-$ collisions at ILC energies can probe the LHM very effectively.

**Appendix:** $A(s, x, \theta_l)$

The expression for energy-angle correlation for the unpolarised beams is given in Ref. [14][15], for the SM and for the BESS models respectively, which may be easily adapted for the LHM. The generalization to include arbitrary beam polarization for each of these models can also be done in a straightforward manner. Here we give it for the LHM. The expressions result from straightforward Dirac trace techniques to include longitudinal beam polarization, by evaluating the electronic part of the Feynman diagrams given in Fig. 1. In particular, for $C_s$ and $C'_s$ the requisite traces which produce the beam polarization dependence associated with them are analogous to those that have been explicitly discussed in ref. [10]. The beam polarization dependence in $C_{int}$ and $C_t$ which we have presented explicitly here, reflect the maximal parity violating nature of the couplings of theWs to the electrons and positrons in the t-channel diagram.

For arbitrary beam we have $A(s, x, \theta_l) = C_s A_s + C'_s A'_s + C_{int} A_{int} + C_t A_t$, with

\[
A_s = -\frac{3}{2} - \frac{3}{2} - \frac{\tau}{x} + \frac{\tau^2}{x^2} + \frac{x}{\tau}\left(1 - x\right)\left(1 + \frac{1}{4\tau}\right)
+ \left(-\frac{5}{2} - \frac{3}{2} + \frac{3}{2} \frac{\tau^2}{x^2} + \frac{1}{2\tau} + \frac{x}{\tau}\left(1 - x\right)\left(1 + \frac{1}{4\tau}\right)\right)\cos^2 \theta_l,
\]

\[
A'_s = 2\left(1 + \frac{1}{4\tau} - 2x - 2x \frac{\tau}{x}\right)\cos \theta_l,
\]

\[
A_{int} = -2\tau + \frac{x}{\tau} - 2 + \frac{x}{2\tau}(1 - x)\left(1 + \frac{1}{2\tau}\right) + \left(1 + \frac{1}{2\tau} - \frac{2\tau}{x} - 2x\right)\cos \theta_l
\]
\(- \left(1 - \frac{1}{2\tau}\right) \left(1 - \frac{x(1-x)}{2\tau}\right) \cos^2 \theta_t\)
\[-Rx^2 \left(2 + (\cos \theta_t - \beta \cos \theta) \times \left(2 - \left(1 + \frac{1}{\tau}\right) \beta \cos \theta + \cos \theta_t\right)\right),\]
\[A_t = \left(-2 + \frac{2x}{\tau} + \frac{x(1-x)}{4\tau^2}\right) + \cos \theta_t \left(1 - (1-x) \frac{x}{2\tau}\right) \cos^2 \theta_t\]
\[\frac{2}{\tau} x^2 R(\beta \cos \theta - \cos \theta_t) \beta \cos \theta + 2x^2 a R^3(\beta \cos \theta - \cos \theta_t)^2.\]

Here
\[R = \left[4\tau^2 + (\beta \cos \theta - \cos \theta_t)(\beta \cos \theta - \beta^2 \cos \theta_t)\right]^{-\frac{1}{2}},\]
\[a = 2\tau - 1 + \beta \cos \theta \cos \theta_t,\]

where \(\cos \theta = 1/\beta (1 - 2\tau/x)\) is the scattering angle of \(W^-\) and \(\beta = (1 - 4m^2_{\text{W}}/s)^{\frac{1}{2}}\) is the velocity of \(W^+\), both in the centre of mass frame. The coefficients, \(C_s\)'s are given below for arbitrary beam polarizations with \(P_{e^-}\) and \(P_{e^+}\) denoting the degrees of electron and positron beams, respectively. In addition to the standard channels (as given in Ref. [14] [15]), these coefficients include the contribution due the \(Z_H\) exchange.

\[C_s = (1 - P_{e^-} P_{e^+}) \left( g_{\gamma WW}^2 \left[ (c_{\gamma c}^v)^2 + (c_{\gamma c}^a)^2 - P \left(2c_{\gamma c}^c\right)\right] + s_Z^2 g_{\gamma ZWW}^2 \left[ (c_{\gamma c}^v)^2 + (c_{\gamma c}^a)^2 - P \left(2c_{\gamma c}^c\right)\right] + s_{ZH}^2 g_{\gamma ZWW}^2 \left[ (c_{ZH c}^v)^2 + (c_{ZH c}^a)^2 - P \left(2c_{ZH c}^c\right)\right] + \right.\]
\[\left. 2s_z g_{\gamma WW} g_{\gamma ZWW} \left[ (c_{\gamma c}^v + c_{\gamma c}^a + c_{\gamma c}^c) - P \left(2c_{\gamma c}^c\right)\right] + \right.\]
\[\left. 2s_{zH} g_{\gamma WW} g_{\gamma ZWW} \left[ (c_{ZH c}^v + c_{ZH c}^a + c_{ZH c}^c) - P \left(2c_{ZH c}^c\right)\right] + \right.\]
\[\left. 2s_z s_{zH} g_{\gamma WW} g_{\gamma ZWW} \left[ (c_{ZH c}^v + c_{ZH c}^a + c_{ZH c}^c) - P \left(2c_{ZH c}^c\right)\right]\right)\]

\[C_s = (1 - P_{e^-} P_{e^+}) \left( g_{\gamma WW}^2 \left[ 2c_{\gamma c}^c - P \left((c_{\gamma c}^v)^2 + (c_{\gamma c}^a)^2\right)\right] + \right.\]
\[s_Z^2 g_{\gamma ZWW}^2 \left[ 2c_{\gamma c}^c - P \left((c_{\gamma c}^v)^2 + (c_{\gamma c}^a)^2\right)\right] + \right.\]
\[s_{ZH}^2 g_{\gamma ZWW}^2 \left[ 2c_{ZH c}^c - P \left((c_{ZH c}^v)^2 + (c_{ZH c}^a)^2\right)\right] + \right.\]
\[2s_z g_{\gamma WW} g_{\gamma ZWW} \left[ (c_{\gamma c}^v + c_{\gamma c}^a + c_{\gamma c}^c) - P \left(2c_{\gamma c}^c\right)\right] + \right.\]
\[2s_{zH} g_{\gamma WW} g_{\gamma ZWW} \left[ (c_{ZH c}^v + c_{ZH c}^a + c_{ZH c}^c) - P \left(2c_{ZH c}^c\right)\right] + \right.\]
\[2s_z s_{zH} g_{\gamma WW} g_{\gamma ZWW} \left[ (c_{ZH c}^v + c_{ZH c}^a + c_{ZH c}^c) - P \left(2c_{ZH c}^c\right)\right]\right)\]

\[C_{int} = g_{\gamma WW}^2 \left( g_{\gamma WW} (c_{\gamma c}^v + c_{\gamma c}^a) + s_z g_{\gamma ZWW} (c_{\gamma c}^v + c_{\gamma c}^a) + s_{zH} g_{\gamma ZWW} (c_{ZH c}^v + c_{ZH c}^a)\right)\]
\[\times (1 - P_{e^-})(1 + P_{e^+})\]

\[C_t = \frac{g_{\gamma WW}^4}{2} \times (1 - P_{e^-})(1 + P_{e^+})\]
Here, the effective polarization, \( P = (P_e - P_{e+})/(1 - P_e - P_{e+}) \), and the propagator factors are defined as: \( s_V = s/(s - m_V^2) \), where \( m_V \) is the mass of the corresponding gauge boson, \( V = Z, Z_H \). We have assumed that the centre of mass energy is sufficiently far away from the threshold regions of the gauge bosons involved.
