Highlights of the Study

- This study aimed to investigate the relationship between tonsilloliths and dental plaque-related pathologies by radiographic examination.
- The number of the missing teeth and periodontal bone loss level was significantly associated with the presence of tonsilloliths.
- The significant results of this retrospective study should be confirmed by clinical trials conducted in a multidisciplinary manner.

Abstract

Objective: The purpose of this study was to analyse the prevalence of tonsilloliths and to determine radiographically whether there is a relationship between tonsilloliths and dental plaque-related pathologies in a series of digital panoramic radiographs. Materials and Methods: This retrospective study included digital panoramic radiographs of 859 patients admitted for routine dental examination. The panoramic images were examined for both the presence of tonsilloliths and the number of decayed, missing, restored teeth and apical periodontitis. Periodontal bone loss was also measured in thirds of optimal bone height according to the root length and a percentage of bone loss was obtained for each panoramic radiograph evaluated. Results: Tonsilloliths were observed in 141 (16.4\%) of all individuals. While there was no significant difference regarding the number of decayed teeth and restored teeth between tonsillolith cases (TT) and cases without tonsillolith (TC), the number of missing teeth and apical periodontitis in TT was significantly higher than TC (\(p: 0.004\), \(p: 0.030\), respectively). There was a significant difference between the groups in terms of the mean percentage of bone loss (\(p: 0.001\); \(p < 0.05\)). In addition, cases showing bone loss between one-third and two-thirds of the optimal bone height in the TT group (52.5\%) were significantly higher than those in TC (45.5\%) (\(p: 0.035\); \(p < 0.05\)).

Conclusion: The relationship between dental plaque-related pathologies and tonsilloliths observed in this retrospective study should be confirmed by computed tomography studies and randomized, prospective, clinical trials conducted in a multidisciplinary manner.

Introduction

Tonsilloliths are dystrophic soft tissue calcifications formed in the crypts of primarily palatine tonsils [1]. The accumulation of desquamated epithelial cells and microorganisms in enlarged crypts, along with deposition of inorganic salts results in tonsillar calcifications. These calcifications most commonly occur in adults and the mean age of occurrence was found to be 46.4 years [2, 3]. They may be single or multiple, unilateral, or bilateral and are usually small in size and asymptomatic. However, individuals with large ones may show symptoms of chronic sore throat, halitosis, tonsillitis, irritation, and discomfort.

Although the exact aetiology and pathogenesis of tonsilloliths are unknown, chronic tonsillar inflammation may trigger their development [4]. Desquamated epithelium, inflammatory exudate, and food debris serve as media for the growth of bacteria, viruses, and fungi [5]. Cooper et al. [2] reported that *Actinomyces* is a common resident of an abnormal tonsil and forms a nidus for calcification. However, a recent study reported that while a strong association was identified between *Actinomyces* and tonsilloliths, this pathological calcification is not based on solely one microorganism because of its polymicrobial nature [6]. A limited number of studies, investigating the bacterial composition of tonsilloliths, focused on heterogeneous microbial composition [7, 8]. Tonsilloliths, as living polymicrobial biofilms, were shown to include *Streptococcus*, *Lactobacillus*, *Actinomyces*, *Eubacterium*, *Fusobacterium*, *Megasphaera*, *Prevotella*, *Selenomonas* and *Tannerella* species, all of which appear to be associated with dental biofilms.

Tonsilloliths are mostly asymptomatic, incidentally found during a routine dental examination. In this context, a panoramic radiograph is a valuable diagnostic tool for the assessment of soft tissue calcifications, considering the broad anatomical view, low cost, and low radiation dose of this imaging modality. On a panoramic radiograph, palatine tonsilloliths may appear as multiple, poorly defined small radiopaque masses superimposed on the ramus of the mandible and surrounding soft tissue [9]. Several recent studies, assessing the prevalence of tonsilloliths on panoramic radiographs, reported a wide range of 0.74–13.4% [9–13].

Considering the similarities between dental biofilm and tonsilloliths, this retrospective study aimed to investigate the prevalence of tonsilloliths and to ascertain radiographically whether there is a relationship between tonsilloliths and dental plaque-related pathologies (e.g., dental caries, apical periodontitis, and periodontal disease) in a series of digital panoramic radiographs.

Materials and Methods

The study protocol was prepared according to the Declaration of Helsinki [14, 15] and it was approved by the Ethics Committee of Kutahya Health Sciences University (Decision Number: 2019/03). This retrospective study included digital panoramic radiographs of patients attending the Department of Maxillofacial Radiology, Faculty of Dentistry, Kutahya Health Sciences University between November 2018 and October 2019 for routine dental examination. Patients under 18 years, those with a history of surgery and trauma, and low-quality radiographs were excluded. The study sample was composed of 859 digital panoramic radiographs (495 [57.6%] were female patients and 364 [42.4%] were male). The average age was 43.42 ± 13.06 years.

Radiographic Analysis

Panoramic radiographs were acquired using a Veraviewepocs panoramic X-ray device (Morita, Kyoto, Japan). The device parameters were set at 8.9 mA and 64 kVp, with an exposure time of 7.4 s. Panoramic images were stored on a desktop computer and all radiographical evaluations were made under standardized conditions (darkened room, without any daylight) by one investigator (E.G.).
The images were examined for the presence of tonsilloliths. Single or multiple radiopacities superimposed on the mandibular ramus and surrounding soft tissue were defined as tonsilloliths (Fig. 1). The location, number, and shape were considered in the differential diagnosis with other soft tissue calcifications such as ossification of stylohyoid ligament, carotid artery calcifications, sialoliths, and calcified lymph nodes [16]. The images were also examined for radiographic evidence of decayed, missing and restored tooth, apical periodontitis, and periodontal bone loss. Periodontal bone loss was evaluated according to Dias et al. [17]. Bone loss was considered when the alveolar crest was found to be 2 mm or more from the cementoenamel junction and measured in thirds of optimal bone height according to the root length. The average of the evaluations of all teeth presenting bone loss was converted to a percentage and the percentage of bone loss was obtained for each panoramic radiograph evaluated. Percentage <0.33 was considered as bone loss less than one-third of the optimal bone height, 0.33 ≤ x ≤0.67 as a bone loss between one-third and two-thirds, and the percentage of more than 0.67 as bone loss more than two-thirds.

### Table 1. Minimum, maximum, mean, standard deviation, and median values of study parameters

| Parameter                  | Minimum | Maximum | Mean ± SD | Median |
|----------------------------|---------|---------|-----------|--------|
| Decayed tooth, n           | 0-14    | 1.59±1.76 | 1         |
| Missing tooth, n           | 0-32    | 7.15±6.34 | 5         |
| Restored tooth, n          | 0-22    | 6.41±4.60 | 6         |
| Apical periodontitis, n    | 0-11    | 1.19±1.36 | 1         |
| Periodontal bone loss, %   | 0-0.98  | 0.34±0.17 | 0.33      |

### Table 2. The number of decayed, missing, restored teeth, and apical periodontitis and the percentage of periodontal bone loss regarding the presence of tonsilloliths

| Parameter                  | TT min–max | Mean ± SD (median) | TC min–max | Mean ± SD (median) | p value |
|----------------------------|------------|--------------------|------------|--------------------|---------|

Mann-Whitney U test. * p < 0.05.

### Results

On digital panoramic images, of the 859 individuals, 141 (16.4%) were found to have radiopaque lesions that were identified as tonsilloliths. Of these subjects participating in the study, 77 were men and 64 were women, and the prevalence of tonsilloliths was 21.2% and 12.9%, respectively. Males presented significantly higher prevalence than females (p: 0.001; p < 0.05). The mean age of pooled tonsillolith cases (TT) (47.13 ± 13.12) was significantly greater than cases without tonsillolith (TC) (42.69 ± 12.93) (p: 0.000; p < 0.05).

Forty-nine cases of tonsilloliths (34.8%) were located on the right side, 37 cases on the left side (26.2%), and 55 cases were bilateral (39%). There was no significant difference in terms of the uni- or bilaterality of tonsilloliths (p: 0.167).

Table 1 summarizes the minimum, maximum, mean, standard deviation and median values of radiographically detected decayed, missing, restored tooth, apical periodontitis, and also periodontal bone loss. Of the 859 individuals, 435 (50.6%) were found to have bone loss less than one-third of the optimal bone height, 401 (46.7%) had bone loss between one-third and two-thirds, and 23 (2.7%) had bone loss more than two-thirds.

The results of the Mann-Whitney U test are displayed in Table 2. While there was no significant difference in...
terms of the number of decayed teeth and restored teeth between TT and TC, the number of missing teeth and apical periodontitis in TT was significantly higher than TC ($p: 0.004, p: 0.030$, respectively). In addition, the mean percentage of bone loss in TT was significantly higher than TC ($p: 0.001; p < 0.05$). There was a statistically significant relationship between the presence of tonsillolith and the percentage of periodontal bone loss.

According to the results of the $\chi^2$ test, cases showing bone loss between one-third and two-thirds of the optimal bone height in the TT group (52.5%) were significantly higher than those in TC (45.5%) ($p: 0.035; p < 0.05$) (Table 3) (Fig. 2). When the evaluations were performed in the age groups (18–40 years, 40–60 years, >60 years) according to the presence of tonsilloliths, no difference was observed in terms of plaque-related pathologies in the groups ($p > 0.05$) (Table 4).

### Discussion

Panoramic radiography, one of the radiographic examinations most used by dentists, is an important tool for the detection of pathological calcifications such as tonsilloliths. We observed tonsilloliths in 16.4% of digital panoramic radiographs in the study population. The prevalence rate is similar to the tonsillolith detection rate (18.5%) reported by Ozdede et al. [18]. However, several studies reported lower prevalence rates (7.2%, 7.3%, 8.14%, respectively) on panoramic radiographs [11, 19, 20]. This discrepancy may be attributed to the racial differences, sample size, variations in the panoramic equipment, imaging modality (analogue vs. digital) and the angulation of the X-ray projection.

We observed that the mean age of the TT group was significantly higher than TC. This result may be associated with the frequent occurrence of chronic tonsillar inflammation in older adults because of the risk factors like smoking and poor oral hygiene [21, 22]. Oral bacteria in secretions in contact with tonsillar epithelium may adhere to the mucosal surface and may stimulate cytokine production by mucosal epithelium [23]. This mechanism, along with poor oral hygiene, may increase susceptibility to tonsillar infection. According to a clinical study, it was shown that the prevalence of the periodontal disease is increased in patients with peritonsillar abscess [24]. Likewise, bacteriologic data demonstrated a relationship between tonsillitis and pericoronitis [25]. The aforementioned

### Table 3. Periodontal bone loss level according to the presence of tonsilloliths

| Periodontal bone loss | TT n | TT % | TC n | TC % | $p$ value |
|-----------------------|------|------|------|------|-----------|
| Less than one-third of the optimal bone height | 60   | 42.6 | 375  | 52.2 |           |
| Between one-third and two-thirds of the optimal bone height | 74   | 52.5 | 327  | 45.5 | 0.035*    |
| More than two-thirds of the optimal bone height | 7    | 5.0  | 16   | 2.2  |           |

$\chi^2$ test. * $p < 0.05$. 

![Graph demonstrating the relationship between the presence of tonsilloliths and periodontal bone loss level.](image)

Fig. 2. Graph demonstrating the relationship between the presence of tonsilloliths and periodontal bone loss level.
tioned studies emphasized the possibility of a causal relationship for these pathologies.

Although small tonsilloliths are mostly asymptomatic, large ones were shown to cause symptoms such as chronic sore throat, tonsillitis, and halitosis [3, 4]. As one of the non-oral reasons for halitosis, this soft tissue calcification was shown to represent a tenfold increased risk for halitosis [26]. Analysis of bacterial composition of tonsilloliths revealed that these calcifications share the same volatile sulphur compound-producing bacteria (e.g., *Porphyromonas*, *Prevotella*, *Fusobacterium*, *Tannerella*), as the origin of halitosis, with the tongue and periodontal pocket [7]. The tonsilloliths were also found morphologically similar to dental biofilm and shown to consist of various bacteria including *Fusobacterium nucleatum* and *Streptococcus sangius* [8]. Similar biofilm colonization is not coincidental in anatomically close regions like the oral cavity and upper respiratory tract.

Considering these similarities and the related causality, it was assumed that the prevalence of tonsilloliths may be associated with the prevalence of dental plaque-related pathologies such as periodontal disease, apical periodontitis, and caries. This study is first radiological study to investigate the relationship between tonsilloliths and dental plaque-related pathologies in terms of reviewing the relevant literature. According to the results of this study, a significant relationship was found between the presence of tonsilloliths and periodontal bone loss level (*p* = 0.035; *p* < 0.05). In addition, the number of missing teeth and apical periodontitis was found to be significantly higher in TT (*p* = 0.004, *p* = 0.030, respectively). Although it was not statistically significant, the number of decayed teeth and restored teeth was higher in TT (*p* = 0.170, *p* = 0.845, respectively). In the light of these data, it can be speculated that for the prevention of tonsillolith formation in susceptible patients, dental practices such as periodontal, endodontic, and restorative treatment may be suggested as they are more advantageous than treatment options for tonsillolith (e.g., tonsillectomy, repeated antibiotic usage) in terms of invasiveness and antibiotic resistance. Thus, the microorganism burden in dental biofilm, which is thought to play a role in the etiopathogenesis of tonsilloliths, can be reduced. However, to draw this conclusion, besides radiological evaluation, in a clinical setting, studies evaluating dental problems of patients exhibiting tonsilloliths are needed. It seems appropriate therefore to conduct multidisciplinary studies, for example, with otolaryngologists.

In addition, the possible relationship between tonsillolith and dental plaque-related pathologies should suggest that halitosis, which does not improve despite restorative and periodontal treatment, may be caused by tonsil-

### Table 4. Evaluations according to the presence of tonsilloliths in the age groups

Mann-Whitney U test.
loliths and hence the patient may need to be referred for otolaryngology consultation. Considering the effect of halitosis on quality of life, it is important for the dentist to be able to recognize the radiopacities that indicate the presence of tonsilloliths in the panoramic radiograph, which is a routine radiographic procedure.

This study has several limitations. Panoramic radiography creates inherent limitations such as superimposition of various structures, distortion, and magnification in the interpretation of tonsilloliths. Also, ghost images may lead to misdiagnosis [3]. However, for a routine dental examination, the central role of this radiological technique has not yet been displaced by the availability of three-dimensional techniques [13]. Moreover, using digital panoramic radiography, image quality can be improved by adjustment of image brightness and contrast [27].

Although panoramic radiography is used more frequently than computed tomography (CT) for a routine examination, CT scans have been found to have higher tonsillolith detection rates than panoramic radiographs [9, 18, 19, 28]. Therefore, it may be more accurate to associate the prevalence of tonsilloliths with dental plaque-related pathologies using CT scans.

Periodontal bone loss, measured from a panoramic radiograph, is not indicative of the current clinical situation. For example, clinical indexes (like plaque index and gingival index) taken from patients could not be evaluated. However, it was shown that there is a close relationship between the clinical periodontal index scores and the bone loss measured from the panoramic radiograph [29]. The result indicating more tooth and periodontal bone loss in older adults with tonsilloliths should be interpreted with caution. As tooth and periodontal bone loss are ageing-related problems, this result may be a coincidence. Lacking a history of periodontal disease, tonsillitis, or any other tonsillar problem as a result of the retrospective design of the study is another limitation. This issue should be considered in future studies.

**Conclusion**

Tooth loss, periodontal bone loss, and formation of tonsilloliths may be confounding factors in the ageing population. Therefore, the relationship between dental plaque-related pathologies and tonsilloliths, observed in this retrospective study, should be confirmed by CT studies and randomized, prospective, clinical trials conducted in a multidisciplinary manner. The prevention or early diagnosis of tonsilloliths may be possible, especially for patients with a predisposition of periodontal disease or tooth loss. Moreover, clinicians should suspect the presence of tonsillolith in the case of unimproved halitosis despite dental treatments.
