Since January 2020 Elsevier has created a COVID-19 resource centre with free information in English and Mandarin on the novel coronavirus COVID-19. The COVID-19 resource centre is hosted on Elsevier Connect, the company's public news and information website.

Elsevier hereby grants permission to make all its COVID-19-related research that is available on the COVID-19 resource centre - including this research content - immediately available in PubMed Central and other publicly funded repositories, such as the WHO COVID database with rights for unrestricted research re-use and analyses in any form or by any means with acknowledgement of the original source. These permissions are granted for free by Elsevier for as long as the COVID-19 resource centre remains active.
Murine encephalitis caused by HCoV-OC43, a human coronavirus with broad species specificity, is partly immune-mediated

Abstract

The human coronavirus HCoV-OC43 causes a significant fraction of upper respiratory tract infections. Most coronaviruses show a strong species specificity, although the SARS-Coronavirus crossed species from palm civet cats to infect humans. Similarly, HCoV-OC43, likely a member of the same coronavirus group as SARS-CoV, readily crossed the species barrier as evidenced by its rapid adaptation to the murine brain [McIntosh, K., Becker, W.B., Chanock, R.M., 1967. Growth in suckling-mouse brain of “IBV-like” viruses from patients with upper respiratory tract disease. Proc. Natl. Acad. Sci. U.S.A. 58, 2268–73]. Herein, we investigated two consequences of this plasticity in species tropism. First, we showed that HCoV-OC43 was able to infect cells from a large number of mammalian species. Second, we showed that virus that was passed exclusively in suckling mouse brains was highly virulent and caused a uniformly fatal encephalitis in adult mice. The surface glycoprotein is a major virulence factor in most coronavirus infections. We identified three changes in the HCoV-OC43 surface glycoprotein that correlated with enhanced neurovirulence in mice; these were located in the domain of the protein responsible for binding to host cells. These data suggest that some coronaviruses, including HCoV-OC43 and SARS-CoV, readily adapt to growth in cells from heterologous species. This adaptability has facilitated the isolation of HCoV-OC43 viral variants with markedly differing abilities to infect animals and tissue culture cells.

Introduction

Until recently, human coronaviruses were mostly associated with mild upper respiratory tract infections (“the common cold”), and occasionally with outbreaks of gastroenteritis (Vabret et al., 2003). However, with the recognition that the Severe Acute Respiratory Syndrome (SARS) was caused by a coronavirus, it became apparent that coronaviruses could also cause more significant disease in the human population (Drösten et al., 2003; Fouchier et al., 2003). Since then, two additional coronaviruses, HCoV-NL63 and HCoV-HKU1, have been identified; these agents cause upper and lower respiratory tract diseases that are much less severe than SARS (van der Hoek et al., 2004; Woo et al., 2005).

HCoV-OC43 and HCoV-229E are the etiological agents for many coronavirus-induced upper respiratory tract infections. HCoV-OC43, harvested from a patient with an upper respiratory tract infection, was originally isolated after passage in human embryonic tracheal organ cultures; this virus caused neurological disease after only one passage in suckling mice and encephalitis within 2–4 passages (McIntosh et al., 1967) (termed HCoV-OC43\textsubscript{NV}). HCoV-OC43\textsubscript{NV} was then propagated in tissue culture cells generating a tissue culture-adapted variant (termed HCoV-OC43\textsubscript{TC}).

HCoV-OC43 showed increasing neurovirulence with passage through the murine brain (McIntosh et al., 1967); however, most recent studies have used CNS-adapted viruses that were further propagated, at least for a few passages, in...
tissue culture cells. For example, Talbot and co-workers showed, using the mouse-adapted virus after passage in tissue culture cells (termed HCoV-OC43QUE herein;) that mice infected intranasally with $10^4-10^5$ TCID$_{50}$ developed encephalitis if inoculated 8 days but not 21 days postnatally (Jacomy and Talbot, 2003). HCoV-OC43QUE was passaged 5–6 times in tissue culture prior to use in mice (personal communication, Dr. Pierre Talbot, INRS-Institut Armand-Frappier, Laval, Quebec) and consequently may be less virulent than virus isolated directly from infected suckling mouse brains. Consistent with this possibility, we observed, in preliminary experiments, that virus directly harvested from suckling mouse brains caused a lethal infection after intranasal inoculation of 5- to 8-week-old mice. Mice died 9–11 days after inoculation, a time when the adaptive immune response to another coronavirus, mouse hepatitis virus (MHV), is maximal (Bergmann et al., 1999). To begin to understand these differences in virulence, we initiated a more complete study of the disease caused by the neurovirulent strain of HCoV-OC43.

This ability of HCoV-OC43 to cross species barriers to infect mice and to gain virulence in the new host contrasts with the strict species specificity exhibited by most coronaviruses. For example, the group I coronavirus HCoV-229E does not readily infect mice, even transgenic mice expressing human aminopeptidase N, the virus receptor for HCoV-229E (Wentworth et al., 2005). However, the ability of the group II coronavirus HCoV-OC43 to adapt easily to replication within the murine brain suggests that it may be more lax in its species specificity than other coronaviruses. In that sense, it resembles another group II coronavirus, SARS-CoV, which likely crossed the species barrier from animals such as palm civet cats to infect humans (CSMEC, 2004; Guan et al., 2003; Song et al., 2005). Unlike other coronaviruses, HCoV-OC43 and the closely related bovine coronavirus (BCoV) appear to bind to cells via N-acetyl-neuraminic acid (Schultze and Herrler, 1992; Vlasak et al., 1988), although there are data to suggest that HCoV-OC43 can also employ MHC class I antigen as a host cell receptor (Collins, 1993). This use of a sugar moiety for entry would also be consistent with the ability to infect a broader range of species than most coronaviruses. This possibility was investigated by infecting tissue culture cells from several different animal species with HCoV-OC43, using both the mouse-adapted and the tissue culture-adapted strains.

The ability to rapidly gain virulence after passage in the murine brain is likely to occur via selection of mutations in the S protein that optimize binding and entry to target cells. Passage of neurovirulent variants of MHV, in tissue culture, selects for viruses that are attenuated in vivo but enhanced for replication in vitro. These changes map to the surface (S) glycoprotein (Gallagher and Buchmeier, 2001; Tsai et al., 2003). In addition, infection of rats with uncloned stocks of MHV resulted in the selection of virulent strains of virus; again, virulence correlated with changes in the S protein (Taguchi et al., 1985). Also, replacement of the S gene in the moderately virulent A59 strain of MHV with the gene encoding the S protein of the virulent JHM strain resulted in a gain in virulence in mice (Phillips et al., 1999). In other studies, several groups showed that the adaptation of the SARS-CoV to humans during the 2003 epidemic included several mutations in the S protein. These mutations were shown to enhance binding to human angiotensin converting enzyme 2 (ACE 2), the host cell receptor for SARS-CoV (Kan et al., 2005; Li et al., 2005). Therefore, to investigate the role of the S protein in HCoV-OC43 pathogenesis, we sequenced the S genes of HCoV-OC43$_{TC}$ and HCoV-OC43$_{NV}$ and compared the results to published sequences of the S genes of several other HCoV-OC43 isolates.

Results

Intranasal inoculation of HCoV-OC43$_{NV}$, but not HCoV-OC43$_{TC}$, is uniformly fatal to 5- to 8-week-old C57BL/6 (B6) mice

In confirmation of our preliminary results, intranasal inoculation of HCoV-OC43$_{NV}$ resulted in 100% mortality in mice ranging from 5 to 8 weeks old (Fig. 1A). Mice developed signs of acute encephalitis, including hunched posture, lethargy and wasting by days 6–7. Mortality was associated with a 30–35% loss of body mass (Fig. 1B). Severe clinical encephalitis was associated with widespread mononuclear cell infiltration including perivascular cuffing and with loss of CNS architecture (data not shown). In contrast, intranasal inoculation of 5-week-old C57BL/6 mice with HCoV-OC43$_{TC}$ did not cause any clinical disease, including any weight loss (Fig. 1). Consistent with the uniformly lethal outcome observed in

Fig. 1. HCoV-OC43$_{NV}$ is uniformly lethal to wild type C57BL/6 mice. 5-week-old mice were inoculated intranasally with 30 LD$_{50}$ HCoV-OC43$_{NV}$ or $10^6$ TCID$_{50}$ HCoV-OC43$_{TC}$ as described in Materials and methods. Mice were monitored daily for survival (A) and weight loss (B). (*Indicates $P<0.0002$).
mice infected with HCoV-OC43NV, we detected high titers of virus in the CNS of infected mice. HCoV-OC43NV grew poorly in tissue culture cells and we could only reliably titer infectious virus using suckling mice, as described inMaterials and methods. Virus titers increased from days 5 to 7 (Fig. 2). To confirm these results, we also measured viral loads using a real-time RT-PCR assay. As shown in Figs. 2A and B, there was a strong positive correlation between recovery of infectious virus and the detection of OC43 nucleocapsid RNA in the brains of mice. Also, and in agreement with the results of Jacomy et al. (Jacomy and Talbot, 2003), HCoV-OC43 infected other organs to a small extent, such as the lungs and intestines, when viral RNA was assayed by real-time RT-PCR (Fig. 2C). Notably, the results also suggested that virus was in the process of clearance at the time of death since virus titers/RNA levels declined between days 7 and 9 p.i. (Fig. 2C).

In mice infected intranasally with neurovirulent strains of MHV, virus enters the CNS via the olfactory nerves with subsequent transneuronal retrograde dissemination to distant connections of the olfactory bulb (Perlman et al., 1989, 1990). Using in situ hybridization and immunohistochemistry to track HCoV-OC43 RNA and antigen, respectively, we detected...
overlap between the pathways of entry and spread used by MHV and those used by HCoV-OC43 after intranasal inoculation. HCoV-OC43 was detected in the olfactory bulb and the olfactory nucleus at 3 days p.i. but was cleared from these structures by day 5 p.i. At later time points (days 7 and 9 p.i.), HCoV-OC43 RNA and antigen were detected primarily in the brainstem and the spinal cord (Fig. 3A, data not shown). Unlike MHV, which is known to infect oligodendrocytes and is present throughout the white matter in the infected CNS, HCoV-OC43 was not detected in the white matter at any time point examined (shown at day 9 p.i. in Figs. 3A, B).

HCoV-OC43\textsubscript{NV} infection of mouse CNS is restricted to neurons

The ability of HCoV-OC43\textsubscript{NV} to cause lethal encephalitis in adult animals contrasted with that reported for HCoV-OC43\textsubscript{QUE}. Jacomy et al. reported that HCoV-OC43\textsubscript{QUE} infection was primarily restricted to neurons in vivo (Jacomy and Talbot, 2003). Thus, one possible explanation for the enhanced neurovirulence of HCoV-OC43\textsubscript{NV} relative to HCoV-OC43\textsubscript{QUE} is an expanded cell tropism. To more directly assess this possibility, we used combined in situ hybridization and immunohistochemistry to identify cell types harboring viral RNA and antigen. We found that viral product was restricted to cells with morphologies consistent with neurons (Figs. 3C, D). Moreover, in some animals evaluated at late times postinfection (day 9), we could clearly identify Purkinje cells that harbored virus antigen (Fig. 3E). When we evaluated whether astrocytes were infected by HCoV-OC43\textsubscript{NV} in vivo, we found no evidence of colocalization of HCoV-OC43 RNA and the astrocyte-specific marker, GFAP antigen (Figs. 3F–H). We also performed a series of colocalization experiments for viral RNA and F4/80, a macrophage/microglia-specific cell marker, but could not identify F4/80\textsuperscript{+} cells that were positive for viral product. To confirm these results, we sorted F4/80\textsuperscript{+}CD45\textsuperscript{hi} (macrophages) and F4/80\textsuperscript{+}CD45\textsuperscript{int} (microglia) cells from the CNS of infected mice at 7 days postinfection, collected them onto glass slides and stained them for virus antigen. Neither macrophages nor microglia stained positive for viral antigen, while infected tissue culture cells processed in parallel stained positively (data not shown). These data suggest that unlike MHV, HCoV-OC43 does not infect astrocytes or macrophages/microglia. Based on the morphology of the infected cells as well as the lack of virus staining in the white matter or in GFAP\textsuperscript{+} or F4/80\textsuperscript{+} cells, we conclude that the predominant, if not sole, targets for HCoV-OC43\textsubscript{NV} are neurons.

Host adaptive immune response contributes to HCoV-OC43\textsubscript{induced} morbidity and mortality

Viral RNA burden in the CNS was diminishing at the time of death (Fig. 2C), consistent with a role for the host immune response in both virus clearance and disease. When we immunophenotyped mononuclear cell infiltrates from HCoV-OC43\textsubscript{NV}-infected mice 7 days postinfection, we found that a large fraction consisted of CD4 and CD8 T cells (Fig. 4A). One
HCoV-OC43-specific CD4 T cell epitope recognized in C57BL/6 mice is known, spanning residues 133–147 of the transmembrane (M) protein (epitope M133). Identification of this epitope was based on sequence homology with MHV. We found that 1–3% of the infiltrating CD4 T cells at day 9 recognized this epitope (Fig. 4B). By contrast, 20–25% of CD4 T cells in the MHV-infected CNS responded to epitope M133 at 7 days p.i. (Haring et al., 2001). No HCoV-OC43 CD8 T cell epitopes have been identified yet so the magnitude of the virus-specific CD8 T cell response could not be determined.

To probe the role of the host adaptive immune response in pathogenesis, we infected immunodeficient mice lacking normal T and B cell responses (mice with genetic disruption of the recombination activating gene 1 (RAG1<sup>−/−</sup>)) and monitored these mice for weight loss and survival. HCoV-OC43<sub>NV</sub>-infected RAG1<sup>−/−</sup> mice developed signs of encephalitis (lethargy, hunching and weight loss) similar to those observed in infected wild type mice, but with delayed kinetics (Fig. 4C, left panel). Infected RAG1<sup>−/−</sup> mice also survived longer than did their B6 counterparts (Fig. 4C, right panel). At the time of death, virus loads were 5–7-fold higher than detected in moribund B6 mice, when measured by real-time RT-PCR (Fig. 4D, left panel) or infectious virus titers (Fig. 4D, right panel). At this time, viral antigen or RNA, detected by immunohistochemistry or in situ hybridization, was detected primarily in the brainstem although more cells were infected than in B6 mice. As in wild type C57BL/6 mice, neurons were the primary target for infection, suggesting that the antiviral immune response was not responsible for the lack of infection of glial cells (data not shown).

To confirm the pathological role of T cells, we adoptively transferred HCoV-OC43-immune cells to RAG1<sup>−/−</sup> mice that

Fig. 4. T cell infiltration into the HCoV-OC43<sub>NV</sub>-infected CNS contributes to morbidity and mortality. (A) Both CD4 and CD8 T cells infiltrate the brains of HCoV-OC43<sub>NV</sub>-infected mice. Mononuclear cells were harvested 7 days p.i., surface stained for CD4 and CD8 and subjected to FACS analysis as described in Materials and methods. Data from one representative mouse are shown. (B) Two color FACS analysis of in vitro peptide-stimulated mononuclear cells demonstrating infiltration of OC43-specific CD4 T cells. Whole brains were isolated from HCoV-OC43<sub>NV</sub>-infected mice 7 days p.i. Mononuclear cells were surface stained for CD4 and intracellularly stained for IFN-γ ex vivo after no stimulation (left panel) or stimulation with M133 peptide (right panel). Data from one representative mouse are shown. (C) HCoV-OC43<sub>NV</sub>-infected RAG1<sup>−/−</sup> C57BL/6 mice lose weight (left panel) and succumb to infection (right panel) with delayed kinetics relative to infected wild type mice (*Indicates P < 0.05). (D) Relative burden of HCoV-OC43 RNA (left panel) and infectious virus (right panel) in brains of moribund wild type and RAG1<sup>−/−</sup> mice. Data in panel C are expressed as mean ± SEM for 4–6 mice per group. (*Indicates P < 0.05).
had been infected with 30 LD₅₀ HCoV-OC43NV intranasally 4 days earlier. HCoV-OC43₅₅₄-infected RAG1⁻/⁻ animals that received no cells died by days 16–18, in line with experiments described above. In contrast, the adoptive transfer of HCoV-OC43-immune splenocytes to RAG1⁻/⁻ mice resulted in death of recipient animals by days 11–13 (data not shown).

Divergent spike glycoprotein gene sequences between mouse CNS-adapted, tissue culture-adapted and primary clinical isolates of HCoV-OC43

While HCoV-OC43₅₅₄ causes lethal encephalitis that is enhanced by the antiviral T cell response, the results described above show that HCoV-OC43₅₅₄ is severely attenuated in mice (Fig. 1). HCoV-OC43₅₅₄ was reported to cause less severe disease than we observed in mice infected with HCoV-OC43₅₅₄. These differences in neurovirulence prompted us to determine the sequence of the S glycoproteins of HCoV-OC43₅₅₄ and HCoV-OC43₅₅₄ and compare them to the published HCoV-OC43₅₅₄ sequence, since the coronavirus S protein is often associated with virulence (Thorp and Galloway, 1979). Included in this comparison are all available sequences submitted for a number of HCoV-OC43 isolates. These additional isolates represent strains that were reported as having been minimally or extensively passaged in tissue culture cells, as well as several primary clinical isolates that were never passaged in tissue culture cells (Supplementary Fig. 1). The sequence alignment revealed substantial divergence in the primary amino acid sequence of these HCoV-OC43 isolates. Of note, there were three amino acid substitutions wholly unique to HCoV-OC43₅₅₄ (Table 1). Multiple other differences between the HCoV-OC43₅₅₄ and HCoV-OC43₅₅₄ or HCoV-OC43₅₅₄ strains are also present in both the S1 and S2 domains (Supplementary Fig. 1). The large number of differences will make it difficult to determine which substitutions are critical for tissue culture cell adaptation. Of note, sequencing of the 3' terminal end of HCoV-OC43₅₅₄ including genes encoding non-structural 12.9 kDa, the small envelope (E), the nucleocapsid (N) and the transmembrane (M) proteins and the 3' untranslated region, revealed no nucleotide differences between HCoV-OC43₅₅₄ and HCoV-OC43₅₅₄.

Table 1

| S protein residue | HCoV-OC43₅₅₄ | HCoV-OC43₅₅₄ | HCoV-OC43₅₅₄ |
|------------------|-------------|-------------|-------------|
| 33 (31,33)       | Serine      | Threonine   | Threonine   |
| 491 (489,495)    | Histidine   | Asparagine  | Asparagine  |
| 759 (757,765)    | Histidine   | Arginine    | Arginine    |
| Virus passage    | Only in     | 5–6 times in| Extensively |
| history          | suckling    | HRT-18 cells| (>10) in    |
| mouse brain      |             | HRT-18 cells|             |
| Neurovirulence   | Uniformly lethal | Lethal only | Avirulent |
| to adult mice    |             | to young    | in mice|
|                  |             | (<21 days)  |             |

* S protein residue numbering is based on HCoV-OC43₅₅₄ strain, with the corresponding residues for HCoV-OC43₅₅₄ and HCoV-OC43₅₅₄ in parentheses. S1 and S2 encompass amino acids 1–759 and 760–1353 to 1365, respectively.

b The sequence for HCoV-OC43₅₅₄ corresponds to GenPept accession number AAT84362, submitted by Sr-Jean et al. (Sr-Jean et al., 2004).

c Jacomy and Talbot (2003).

d Fig. 1.

As described above, HCoV-OC43 differs from most strains of coronaviruses in that it readily crosses species barriers to infect mice (McIntosh et al., 1967). This observation raised that possibility that HCoV-OC43, unlike most other coronaviruses, is able to infect a wide variety of species without substantial adaptation. To gain insight into this possibility, we infected a variety of tissue culture cells from a wide range of species (hamster, pig, human, mouse, rat, monkey and cat) with HCoV-OC43₅₅₄ or HCoV-OC43₅₅₄. As shown in Fig. 5, immunocytochemical staining for viral antigen revealed that the tissue culture-adapted virus infected hamster, pig, human, mouse, monkey and cat cells, but not FRT rat epithelium cells. The neurovirulent strain also exhibited a wide host range specificity, infecting hamster, pig, human, monkey, cat and mouse cells. For some cell lines, such as murine 17CL-1, and human KB and HT1080 cells, we detected infection only by the tissue culture-adapted variant. Thus, both HCoV-OC43₅₅₄ and HCoV-OC43₅₅₄ showed broad species specificity, and not surprisingly, HCoV-OC43₅₅₄ showed enhanced ability to infect all types of tissue culture cells. Whether animals from these various species are also infectable by HCoV-OC43 remains to be determined, although data suggesting a close relationship between HCoV-OC43 and BCoV (Vijgen et al., 2005b) make it likely that the virus would be able to infect other species after minimal adaptation.

Discussion

HCoV-OC43, as demonstrated herein, infects many cell types and readily adapts to cause a virulent infection in mice (Jacomy and Talbot, 2001, 2003) (Fig. 1). BCoV, which is closely related to HCoV-OC43, also infects mice (Akashi et al., 1981; Barthold et al., 1990); phylogenetic analyses suggest that the two viruses diverged as recently as 1891 (Vijgen et al., 2005b). These results suggest that HCoV-OC43 or BCoV crossed species from either humans or bovine to infect the other species, although the direction of spread is not known. This ability to cross species is also shared by SARS-CoV. SARS-CoV spread from exotic animals, most likely palm civet cats, to humans during contacts in “wet markets” in China (Peiris et al., 2004). Also, as part of efforts to study the pathogenesis of this virus and to develop vaccines, several animal species, including mice, cats, ferrets and monkeys were shown to be susceptible to infection with the virus (Peiris et al., 2004). SARS-CoV did not cause reproducible disease in any of these species, suggesting that further adaptation was required for optimal virus replication in these heterologous species. HCoV-OC43 and SARS-CoV differ from many coronaviruses, exemplified by HCoV-229E, in their ability to cross species.
Fig. 5. Broad tissue and cell type tropism of HCoV-OC43. A wide variety of tissue culture cells from hamster, rat, pig, human, mouse, monkey and cat were infected with 10 TCID₅₀ (10⁵ SMLD₅₀) of HCoV-OC43₅₀ or 30 TCID₅₀ of HCoV-OC43₇₈ or mock-infected as described in Materials and methods. After 3 days, virus-infected cells were detected with immunocytochemistry as described in Materials and methods. Nearly all of the cell lines were infected with both viruses, demonstrating that HCoV-OC43 exhibits a broad species specificity in vitro. Original images are 20× magnification.
HCoV-229E, a human respiratory virus, does not infect mice or even mice transgenic for human aminopeptidase N (hAPN), the HCoV-229E host cell receptor (Wentworth et al., 2005). However, infection occurs, albeit with mild clinical disease if virus is adapted for growth in murine cells expressing hAPN and if mice are deficient in type I interferon responses (Lassnig et al., 2005).

SARS-CoV and HCoV-OC43, while both able to cross species, differ in regard to host cell receptor usage. The primary receptor for SARS-CoV is angiotensin converting enzyme 2 (ACE2) and other molecules such as DC-SIGN serve to enhance binding to target cells (Jeffers et al., 2004; Li et al., 2003; Marzi et al., 2004). Adaptation to growth in foreign species involves mutations that enhance binding to heterologous ACE2 (Li et al., 2005). No proteinaceous receptor for HCoV-OC43 has been conclusively identified; rather, O-acetylated sialic acid or a closely related compound appears to serve as the host cell receptor (Schultze and Herrler, 1992; Vlask et al., 1988). While little is known about the changes required for efficient replication of HCoV-OC43 in the murine CNS, it is likely that this process includes mutations that affect binding to host cell sugar moieties. Infection with the prototypic alphavirus, Sindbis virus (SINV), or with a picornavirus, Theiler’s murine encephalomyelitis virus (TMEV), is initiated by binding to a polyanionic polysaccharide, heparin sulfate (Byrnes and Griffin, 1998; Klimstra et al., 1998; Reddi and Lipton, 2002). SINV with enhanced binding to heparin sulfate is selected after passage in tissue culture cells. HCoV-OC43 may undergo a similar set of changes during the course of adaptation to growth in tissue culture cells. The S protein of HCoV-OC43 differs from that of HCoV-OC43NV at 20 positions (Supplementary Fig. 1), making it difficult to determine which ones might contribute to enhanced ability to replicate in tissue culture cells.

By contrast, HCoV-OC43NV includes a limited number of amino acids that are not present in any S proteins described in the literature (Table 1 and Supplementary Fig. 1). In all laboratory isolates of HCoV-OC43, viruses encoding these proteins were passaged at least a few times in tissue culture cells (Kunkel and Herrler, 1993b; Kunkel and Herrler, 1996; Mounir and Talbot, 1993; St-Jean et al., 2004; Vijgen et al., 2005b). While no two sequences are identical, three substitutions, T33S, N491H and R759H, are unique to the HCoV-OC43NV strain (Table 1 and Supplementary Fig. 1). The receptor binding domain of HCoV-OC43 has not been defined, but both T33S and N491H are in regions important for receptor binding by other coronaviruses (e.g., Saeki et al., 1997; Xiao et al., 2003). Thus, these two changes could potentially alter the association or stability between HCoV-OC43NV and host cell receptors in the murine CNS.

In other coronaviruses, cleavage of S into S1 and S2 domains is required for optimal virus replication. For example, disruption of the S1–S2 cleavage site in MHV resulted in a viable virus that was attenuated for growth in tissue culture cells and mice (Stauer et al., 1993; Taguchi, 1993). On the other hand, studies in BCoV revealed no correlation between the presence of the furin cleavage motif and virulence (Zhang et al., 1991). Of the several laboratory isolates of HCoV-OC43 that have been sequenced, most contain the sequence RRSRG at the putative furin cleavage site. Kunkel and Herrler showed that S proteins containing this motif are not cleaved in infected cells, whereas two strains (designated OC43-CU and OC43-VA, Supplementary Fig. 1) in which the S gene encoded a prototypic cleavage site (RRSRR) were cleaved (Kunkel and Herrler, 1993a). The sequences of seven recently described primary clinical isolates also share the RRSRR motif (Supplemental Fig. 1) (Vijgen et al., 2005a). Whether or not these primary isolates are cleaved and whether this motif contributes to clinical disease in humans is not known. As reported herein, the S protein of HCoV-OC43NV contains the sequence RRSHG and presumably is not cleaved to a significant extent because it contains a glycine at position 5; it is even less likely that HCoV-OC43TC, in which the sequence at this site is IRSRG, is cleaved. Although the R759H substitution is unlikely to affect cleavability of HCoV-OC43NV S, as this is a conserved (charged-basic to charged-basic) change, it is formally possible that this unique substitution could alter cleavage and contribute to the enhanced virulence of HCoV-OC43NV.

The position of these 3 mutations (T33S, N491H, and R759H) is consistent with a role in virulence, but to prove definitively their role in disease enhancement, it will be necessary to introduce these changes into the HCoV-OC43 genome. This will require a reverse genetics system. An infectious clone for HCoV-OC43 has not yet been reported, but it is likely that one or more infectious cDNA clones will be available in the near future.

While a comparison of our results with those of Jacomy et al. suggest that HCoV-OC43NV is more virulent than HCoV-OC43QUE, both strains show a tropism for neurons (Jacomy and Talbot, 2003). Direct virus destruction of infected neurons is clearly important for much of the disease observed in mice infected with HCoV-OC43NV or HCoV-OC43QUE; even though death is delayed in infected RAG1−/− mice compared to wild type mice, all mice still die by 16 days p.i. (Fig. 4). However, the delayed death of infected RAG1−/− mice suggests that HCoV-OC43-induced encephalitis is in part mediated by the antiviral T cell response. Of note, Jacomy et al. previously concluded that the adaptive immune response did not contribute to pathology associated with HCoV-OC43 infection, based on the observation that treatment of mice with cyclosporin (CsA) prior to infection resulted in more rapid onset of disease and an increase in the percentage of mice that succumbed to the virus (Jacomy and Talbot, 2003). These contrasting results may result from the different mechanisms of immunosuppression observed in RAG1−/− and CsA-treated mice.

Neurons do not normally express MHC class I or II antigen and express only low levels of the machinery required for loading peptide onto MHC class I antigen (Joly and Oldstone, 1992). However, electrically silent or damaged neurons do express MHC class I antigen (Medana et al., 2000; Neumann et al., 1995, 1997) and it is possible that infection with HCoV-OC43 makes neurons into suitable targets for CD8 T cells.
note, even damaged neurons have never been reported to express MHC class II antigen, making a direct effect of CD4 T cells on infected neurons unlikely. However, CD4 T cells are required for optimal function of CD8 T cells in the MHV-infected CNS (Stohlman et al., 1998). Sindbis virus (SINV), a prototypic alphavirus, also primarily affects neurons. While virus clearance is largely mediated by antiviral antibodies, T cells, by secreting IFN-γ, are critical for clearance from spinal cord neurons (Binder and Griffin, 2001). Similar mechanisms may be involved in virus clearance from HCoV-OC43 neurons, with subsequent immunopathology. Future studies, directed at determining whether antiviral CD4 and CD8 T cell responses contribute to both virus clearance and to severe disease in HCoV-OC43-infected mice, may also be relevant to understanding disease outcome in patients with SARS, since neurons are infected in some patients (Gu et al., 2005).

Materials and methods

Viruses and cell lines

HCoV-OC43SV and HCoV-OC43TC (VR-759 and VR-1558, respectively), as well as the cell lines 17Cl-1, L929, HeLa and AK-D, were obtained from the ATCC (Manassas, VA). FRT, CHO-K1 and LLCK-PK cells were a generous gift from Dr. Michael Welsh, University of Iowa. HCoV-OC43 VR-759 was propagated in suckling mouse brain. HCoV-OC43 VR-1558 was propagated in HRT-18 cells.

Mice

Pathogen-free male C57BL/6 mice were purchased from the National Cancer Institute (Bethesda, MD). RAG1+/− and suckling Swiss mice were obtained from breeding colonies maintained by our laboratory. For intranasal infection, 5- to 7-week-old mice were lightly anesthetized with halothane and droplets containing 30 LD50 (107 SMLD50) of HCoV-OC43NV or 105 SMLD50 (approximately 10 TCID50 based on infection of HRT-18 cells) were inoculated intranasally into 2- or 3-day-old Swiss pups. Survival was monitored and viral titers were calculated using the formula of Karber: Negative log of the lowest dilution − [(sum of percentage positive / 100) − 0.5] × log interval. Virus titers are expressed as the reciprocal of the highest dilution where the virus suspension killed 50% of inoculated suckling mice (SMLD50).

Virus antigen detection

For immunohistochemistry, brain and spinal cord sections were processed as previously described (Pewe et al., 2002). Primary antibody was mouse anti-S mAb (O.4.3) and secondary antibody was biotinylated goat anti-mouse. Sections were developed by sequential incubation with streptavidin–horseradish peroxidase (HRP) conjugate and DAB reagent (Sigma, St Louis, MO) or streptavidin–Cy3 reagent (Jackson ImmunoResearch, West Grove, PA). For immunocytochemistry of OC43-infected adherent cells, samples were fixed for 30 min in 10% formalin, rinsed with 100 mM glycine and permeabilized in 0.5% Triton X-100. Wells were blocked with 10% NGS and incubated with O.4.3 overnight at 4 °C. Wells were developed as described above.

In situ hybridization

8 μm brain and spinal cord sections were prepared as described above and in situ hybridization for viral RNA was performed using a protocol adapted from Gene Detect (Auckland, New Zealand). Briefly, formalin fixed, paraffin embedded tissue sections were permeabilized for 30 min at 37 °C in 250 μg/ml pepsin in 200 mM HCl and then blocked with prehybridization buffer for 2 h at 37 °C. 3′-biotinylated, HCoV-OC43-specific oligonucleotide probes (antisense 5′–3′, GATAATGACATCAGCCTGTTGCTAG; sense 5′–3′, CTA-GCAACCAGGCTGATGTCAATA) were added to a final concentration of 200 ng/ml and sections were incubated for 18 h at 37 °C. After several washes of increasing stringency, streptavidin–HRP conjugate was added for 1 h at 25 °C followed by tyramide signal amplification (TSA) cyanine 3 reagent (Perkin Elmer, Boston, MA). For some experiments, slides were also stained with anti-GFAP followed by FITC-
conjugated goat anti-rabbit secondary antibody prior to developing with TSA-Cy3 reagent. Sections were examined with a Bio-Rad (Hercules, CA) LaserSharp2000 confocal microscope.

**Real-time RT-PCR**

Total RNA was isolated using Tri Reagent (Molecular Research Center, Cincinnati, OH) following the manufacturer’s instructions. 2 μg of total RNA was reverse transcribed to cDNA using RETROscript RT-PCR Kit (Ambion, Austin, TX) according to the manufacturer’s instructions. The resulting cDNA was subjected to PCR as follows. 2 μl of cDNA was added to a 23 μl PCR cocktail containing 2× SYBR Green Master Mix (Applied Biosystems, Foster City, CA) and 0.2 μM of each sense and antisense primers (Intergated DNA Technologies, Coralville, IA). Amplification was then performed in an Applied Biosystems Prism 7700 thermocycler. Specificity of the amplification was confirmed using melting curve analysis. Data were collected and recorded by the Prism 7700 software and expressed as a function of Threshold Cycle (Ct). Specific primer sets used for HCoV-OC43 and murine housekeeping gene are as follows (5′ to 3′); HCoV-OC43 nucleocapsid forward, GGTCTCAACCCCACTAGT; OC43 nucleocapsid reverse, TGA TGCTTATG GCTTCA; HPRT forward, CCTCATGAGTATTGGA; HPRT reverse, CAGATCAACTGGCTCATC. HCoV-OC43 nucleocapsid RNA abundance was calculated using methods described previously (Pewe et al., 2005).

**Sequencing**

Total RNA from infected murine brain or A549 cells was reverse transcribed to cDNA. Primers were designed (based on GenBank accession number AY585228) to generate overlapping amplimers, ensuring complete coverage (7700 software and expressed as a function of Threshold Cycle (Ct)). Specific primer sets used for HCoV-OC43 and murine housekeeping gene are as follows (5′ to 3′); HCoV-OC43 nucleocapsid forward, GGTCTCAACCCCACTAGT; OC43 nucleocapsid reverse, TGA TGCTTATG GCTTCA; HPRT forward, CCTCATGAGTATTGGA; HPRT reverse, CAGATCAACTGGCTCATC. HCoV-OC43 nucleocapsid RNA abundance was calculated using methods described previously (Pewe et al., 2005).

**Flow cytometry**

Single cell suspensions of mononuclear cells from whole brain homogenates were prepared as previously described (Pewe et al., 2005). Fc receptors were blocked with normal rat serum and anti-CD16/CD32 (clone 2.4G2, BD Biosciences, San Jose, CA). Antibodies used to phenotype cells were fluorescein isothiocyanate-labeled anti-mouse CD4 and phycoerythrin-labeled anti-mouse CD8 (clones GK1.5 and 53–6.7, BD Biosciences, Mountain View, CA). CD4 T cells recognizing an HCoV-OC43-specific CD4 T cell epitope M133 (spanning residues 133–147 of the M protein) were identified using intracellular cytokine staining as previously described (Wu et al., 2000). Samples were analyzed on a FACScan flow cytometer (BD Biosciences, Mountain View, CA).

**Statistics**

Statistical analysis was done with unpaired (two-tailed) *t* tests. Values in figures are expressed as mean ± SEM. Values of *P* < 0.05 were considered significant and are indicated by an asterisk (*). In figures.
