Abstract

Adults and larvae of *Leptotrachelus dorsalis* (Fabricius), the Sugarcane Savior Beetle, live in association with grasses, the larvae in the appressed leaf axils. Both adult and larval *L. dorsalis* eat larvae of the Sugarcane Borer, *Diatraea saccharalis* (Fabricius), and perhaps other insects living in the confines of the leaf sheaths of that and other grass-like species. The geographic range of *L. dorsalis* extends from Kansas in the west to the Atlantic seaboard, north as far as Ontario, Canada and south to Cuba; it is an eastern species of North America and the Caribbean. Larval character attributes that are shared with a related ctenodactyline, *Askalaphium depressum* (Bates), provide a preliminary basis for characterization of the immatures of tribe Ctenodactylini.

Keywords

Sugarcane Savior Beetle, Louisiana, commensalism, Sugarcane, *Saccharum officinarum* L., Sugarcane Borer, *Diatraea saccharalis* (Fabricius)

Resumen

Los adultos y larvas de *Leptotrachelus dorsalis* (Fabricius), el Escarabajo Salvador de la Caña de Azúcar, viven asociados a hierbas, las larvas en las axilas de las hojas recostadas. Tanto el adulto como la larva de *L. dorsalis* se comen la larva del Taladrador de la Caña de Azúcar, *Diatraea saccharalis* (Fabricius), y quizás otros insectos más que viven en los confines de la vaina de la hoja de esta y otras especies de gramíneas. La distribución geográfica de *L. dorsalis* se extiende desde Kansas en el oeste hasta el litoral del Atlántico, hacia el norte hasta Ontario, Canadá, y hacia el sur hasta Cuba; es una especie del este de América del Norte y el Caribe.
Los atributos de los caracteres larvales que son compartidos con un ctenodactylinio, *Askalaphium depressum* (Bates), proveen una base preliminar para la caracterización de los inmaduros de la tribu Ctenodactylini.

**Introduction**

*Leptotrachelus dorsalis* (Fabricius) is known to occur in Canada – ON; Cuba; and the USA – AL, AR, CT, DC, DE, FL, GA, IA, IL, IN, KS, KY, LA, MD, MI, MN, MO, MS, NC, NJ, NY, OH, PA, SC, SD, TN, VA, and WV. According to Lindroth (1969), adults (Fig. 2) are found at the borders of pools and ponds where the vegetation is tall and rich, e.g., in cattail (*Typha latifolia* L.) swamps (Fig. 1) with tufts of *Carex rostrata* Stokes, *Menyanthes* sp., *Solanum dulcamara* L., and others. Adults take cover within the leaf axils of *Typha latifolia* stems. Adults are attracted to lights. In sugarcane, they are found within the canopy (top quarter) of the plant, the region of the sugarcane plant where the Sugarcane Borer, *Diatraea saccharalis* (Fabricius) lays its eggs and where the neonate larvae become established behind the leaf sheaths of elongating internodes. Larvae of *L. dorsalis* are rarely encountered below this region, as young Sugarcane Borer larvae are also rarely encountered in association with the lower mature internodes.

Erwin and Medina (2003) wrote: “Van Emden (1942) described the larva of *Leptotrachelus dorsalis* (Fabricius), Ctenodactylini, the only known larva of the tribe until now. However, at that time “Colliurina” and “Ctenodactyлина” were regarded
as subtribes of Colliurini (Colliurini is now classified as an unrelated clade, Oda-
canthini), thus van Emden inadvertently gave a single combined description for
both tribes, and then provided in a key the means of which to separate what he
regarded as subtribes, but with very few important features listed. Van Emden pro-
vided illustrations for many other genera in his important contribution to knowl-
gedge of carabid larvae, but did not provide any for these particular ctenodactyline
and odacanthine groups.”

Now that we have reared specimens (all stages except egg), we realize that Van
Emden’s description is not that of purely *Leptotrachelus dorsalis* individuals.

Thompson (1979) summarized van Emden’s description, but did not add any-
thing new to it, did not provide illustrations of any Ctenodactylini, nor did he sort the
mixed characters of the two tribes. He did provide illustrations (heads of L₁ and L₃ and
cerci) of *Colliurus pensylvanicus* L. along with a reasonably complete description. These
tribes, Ctenodactylini and Odacanthini, however, are now recognized as not being
especially closely related (Erwin 1991).

Bionomics of *Leptotrachelus dorsalis* are discussed in a separate paper (White et al.
in press). Here we provide larval and pupal descriptions of the Sugarcane Savior Beetle
and notes on the taxonomic complementarity of *Leptotrachelus* and *Askalaphium* larvae
as a beginning in understanding the immature forms of Ctenodactylini.

**Specimens and methods**

Specimens were initially obtained from experiments to determine economic thresholds
for Sugarcane Borer in new sugarcane cultivars (White et al. 2008).

Descriptive and larval preparation methods follow those suggested by the classic
carabid larval method paper of Bousquet and Goulet (1984), particularly their coding
system for setae and pores in L₁ larvae, and their description format, believed to be
ancestral in carabids. Additional setal and pore positions were discovered in Cteno-
dactylini (Erwin and Medina 2003) and were designated in a sequence that follows the
methods suggested by Bousquet and Goulet (1984). However, we have not attempted
that here since we do have the first instars. Those subsequent designations in Erwin
and Medina (2003) may be merely accessory setae common in later instars. All *Lep-
totrachelus dorsalis* immature specimens illustrated here are from populations in the
environs of Houma, LA. They were reared in the laboratory from eggs laid by wild
captured adults in sugarcane plantings. Many additional larvae were hand collected in
the leaf axils of standing sugarcane, as well.

**Tribe Ctenodactylini**

(The following is based on larvae of *Askalaphium depressum* (Bates) and *Leptotrachelus
dorsalis* (Fabricius), the only confirmed described larvae in the Tribe).
**Recognition.** (See Erwin and Medina 2003, and Fig. 14 herein for illustrations of *A. depressum*) Head and body depressed, markedly so in *A. depressum*, much less so in *L. dorsalis*. Head wider than prothorax in *A. depressum*, coequal in width in *L. dorsalis*. First instars of *A. depressum* unknown, in first instar of *L. dorsalis* frontal piece with long U-shaped row of short stiff setae likely used as an egg burster. Frontale slightly produced medially, toothed or shallowly bilobed. Neck slightly to moderately constricted, short and broad, cervical groove and keel distinct. Mandible with inner edge of blade and posterior margin of retinaculum moderately serrate (3rd instar). Maxilla with inner lobe present, unisetose, seta 2× length of lobe in *A. depressum*, absent and devoid of seta in *L. dorsalis*. Labium markedly produced medially and unisetose. Antennomere 3 with small tubercule laterad near apex (not a hyaline bulb). Segment IX with two stout curved setae ventrally; urogomphi non-segmented, multi-nodose, infuscated. Pygopod with marked triangular patch of setae postero-ventrally.

Leptotrachelus dorsalis (Fabricius, 1801)
http://species-id.net/wiki/Leptotrachelus_dorsalis

Description of first and third instars. Coloration (as in Fig. 3). Mostly pale cream color with infuscated head capsule, mandibles, and urogomphi, the latter with pale spots; other mouthparts, antennae, and pronotum slightly darker than rest of body.

Microsculpture. Head capsule without visible sculpticels.

Form. Head (Figs 3, 4, 8). Nasale moderately produced, quarto-dentate, teeth co-equal in length; mandibles robust and with obvious serrations medially on blade and posterior to retinaculum; genae not prominent, very slightly wider than distance across stemmata, slightly narrowed to broad neck. Eyes of 6 barely prominent stemmata. Antennomere slightly shorter than porrect mandible; antennomere 2 slightly shorter than 1, 3, and 4. Mandible with prominent retinaculum, curved dentiform; terebral blade obviously serrate, pensillus absent. Ligula of labium slightly produced, unisetose, labrum ventrally sextasetose. Ratios of palpmere lengths can be deduced from the illustrations.

Thorax. (Figs 3, 5, 9). Prothorax narrowly quadrate (L₁), more broadly quadrate (L₃); meso- and metathorax transverse trapezoid, narrow anteriad, broader posteriorly.

Abdomen. (Figs 3, 6, 7, 10, 11). Segments hexagonal, broad. Urogomphi about one and a half times as long as prothorax is long.

Legs. (Figs 3, 12). Tarsus unispinose at apex and with a single seta at midpoint dorsally.

Chaetotaxy (L₁). Head. Frontale (Fig. 4) with 7 setae (FR₁ – FR₇) on each side; and 2 pores (FRc & FRe) on each side; egg burster a lyre-shaped row of short setae. Parietale (Figs 4A, 4B) with 19 setae (PA₁ – PA₁₉) and 5 pores (PAc, PAj, PAk, PAm, PAN) on each side. Antenna (Fig. 4A): antennomere 1 with 3 pores (unlabeled); antennomeres 2 – 4 with no pores; antennomere 3 with 3 setae (AN₁ – AN₃) and 1 small

sensilla near base of sensorial appendage (Fig. 4A); antennomere 4 with 4 setae (AN1–AN4) and 2 small apical sensillae (Fig. 4A). Mandible (Fig. 4A) with 1 seta (MN1) and 2 pores (MNb–MNc). Labium (Fig. 4B): prementum with 3 setae (LA2, LA3, LA7) and 1 pore (LAa) on each side; palpomere 1 with 1 pore (LAb); palpomere 2 and 3 without visible features. Maxilla (Fig. 4B): cardo without setae; stipes with 3 constant setae (MX2, MX3, MX4); 5 pores (MXa–MXc), others not labeled; lacinia and galeomeres without setae and pores; maxillary palpomeres without visible sensatory features.

**Thorax.** Prothorax: Notum (Fig. 5A) with 10 major setae (PR2–4, 6, 8–13), PR1, 5, 7 absent, and 3 pores (PRc only named one) on each side; pleurite (Fig. 5B) with 3 setae (PL9, 10, 11), and no pores on each side; episternum (Fig. 5B) with 3 setae (unnumbered).
Figure 7. Larval abdomen (L₁), of *Leptotrachelus dorsalis* (Fabricius). **A** dorsal aspect **B** ventral aspect. Abdominal segments **A-7** through **A-10**; and cerci and pygidium. Scale line equals 0.5 mm.

Mesothorax: Notum (Fig. 5A) with 14 setae (ME1 – ME14), 3 small auxiliary setae, and 1 pores (MEg) on each side; episternum (Fig. 5B) with no setae and no pores; epimeron (Fig. 5B) with 1 seta (EM1); pleurite (Fig. 5B) with 3 posterior seta (PL1, 5, 6); sternum (Fig. 5B) with 1 seta (not numbered) and no pores on each side.

– FE6), 1 unnumbered accessory seta and no pores. Tibia (Fig. 12) with 6 setae (T1 – T7, T6 missing) and no pores. Tarsus (Fig. 12) 2 segmented, with 6 seta (T21 – T26) and 1 unnumbered accessory seta and no pores on T2, and 1 constant seta on T1 and 1 unnumbered accessory seta and no pores. Claws (Fig. 12) with 1 seta near base.

**Description of pupa.** See Fig. 13. Typical of known carabid pupae, not many of which have been illustrated and described. Note the exceedingly setiferous ocular area of head and cerci.
Characteristics of Ctenodactylini larvae. Erwin and Medina (2003) showed that van Emden (1948) mixed attributes of two unrelated tribes, Odacanthini (Colliurini) and his concept of Ctenodactylini. They found that $L_3$ members of the genus *Leptotrachelus* contain the following larval attributes found in larvae of *A. depressum*: epicranial suture short; cervical groove and keel present; maxilla with inner lobe present; neck not severely constricted; urogomphi nodal, yet not segmented. They located the collection of *L. dorsalis* larvae that van Emden studied (collected at Oxford, Indiana) in the NMNH, however, they are not in very good condition. They also confirmed his observations and added that second and third instars lack a pencillus and the terebral blade is micro serrate, but refrained from making a more detailed comparison until better specimens were discovered. These observations are now testable with the wealth of material found by the junior author in Houma, Louisiana. Our understanding of the structural attributes of the larval stages for the carabid tribe Ctenodactylini is now progressing.

Erwin and Medina (2003) also studied some poorly preserved specimens of *Odacanta melanura* L. in the NMNH collection. These specimens differ from ctenodactyline larvae in that the mandible has a single seta pensillus and the maxilla lacks an inner lobe, other features are not discernible. Undescribed larvae of some genera of ctenodactylines were also found in the rotten stems and leaf axils of species of the plant genera *Heliconia* L. and *Calathea* G. Mey in low wet places in Amazonian Ecuador and Perú. Adults of *Ctenodactyla* Dejean occur on species of these plants at night. Further
discovery is necessary and subsequent documentation is required to define more accurately the Ctenodactylini, and to explore the patterns that must link these beetles evolutionarily and ecologically to the plants on which they live and the food which they eat.

Conclusions

The hypothesized “home reed,” *Typha latifolia* L., as a microhabitat for this commensal species of carabids is classified in the Poales, Typhaceae. This reed, commonly called bulrushes or cattails, is an obligate wetland species and has been found in a variety of climates, including tropical, subtropical, southern and northern temperate, humid coastal, and dry continental up to 2300 m altitude in North, Middle, and South America. However, we point out that species of *Leptotrachelus* are known to occur commonly as adults on the culms of marsh grasses such as *Panicum dichotomiflorum* (*Leptotrachelus dorsalis*: Steiner 1984) in Maryland, USA, and *Paspalum* sp. (*Leptotrachelus* spp.: Erwin 1991) in the western Amazon Basin. There are currently 40 described species of *Leptotrachelus* in the Western Hemisphere, all with proximity to the spread of sugarcane plantations. In these plantations, there are often water-filled ditches with bulrushes and this is the likely source of the beetles that invade the standing canes; it is also a refuge for the beetles when the sugarcane fields are harvested in the fall and winter and resulting residues are burned off, a usual practice. They maintain their populations there in the

![Figure 13. Pupa of *Leptotrachelus dorsalis* (Fabricius). A dorsal aspect B left lateral aspect C ventral aspect. Scale line equals 1.0 mm.](image-url)
Carabid beetle species associated with Sugarcane

bulrushes and reinvade the sugarcane ratoons in the spring, or after the next planting cycle. This makes them excellent biocontrol agents; however, broad spectrum pyrethroid insecticides sometimes used by farmers and predation by the red imported fire ant, *Solenopsis invicta* Buren, can severely reduce beetle numbers.
