Highlights of the Study

- This study shows that invasively measured fractional pulse pressure is associated with acute kidney injury (AKI).
- Fractional pulse pressure is an independent predictor of AKI in STEMI patients.
- The in-hospital mortality rate is significantly higher in patients with AKI than those without.

Fractional pulse pressure · Acute kidney injury · Myocardial infarction · ST-segment elevation myocardial infarction

Abstract

Objective: Acute kidney injury (AKI), which is prevalent in ST-segment elevated myocardial infarction (STEMI) patients who have undergone primary percutaneous coronary intervention (PCI), is associated with poor cardiovascular outcomes. As high pulse pressure (PP) is associated with adverse cardiovascular events, the present study’s aim was to evaluate the relationship between fractional PP (PPf) and AKI in patients with STEMI who underwent primary PCI. Subjects and Methods: All laboratory findings as well as echocardiographic and angiographic data of 1,170 consecutive STEMI patients were retrospectively screened. PPf was calculated from the pressures invasively measured after sheath insertion and before performing coronary angiography. Results: From 1,170 eligible STEMI patients (mean age 56 years, 18.2% female), AKI developed in 143 (12.2%) patients. The PPf and pulsatility index were significantly higher in patients with AKI than those without (0.53 ± 0.10 vs. 0.61 ± 0.10, \(p < 0.001\), and 0.80 ± 0.03 vs. 0.82 ± 0.03, \(p < 0.001\), respectively). PPf was also found to be associated with AKI in univariable (OR 2.183, 95% CI 1.823–2.614, \(p < 0.001\)) and multivariable (OR 1.874, 95% CI 1.513–2.322, \(p < 0.001\)) analysis. In-hospital mortality was higher in patients with AKI than those without. Conclusion: Invasively measured PPf, which can be easily measured and has no additional cost in STEMI patients undergoing coronary intervention, is an independent predictor of AKI. In addition, PPf is superior to other blood pressure values and derivatives in AKI prediction.
Introduction

Contrast media that is widely used in many diagnostic and interventional procedures may cause acute kidney injury (AKI) because of its known nephrotoxicity. The incidence of AKI in cardiovascular procedures ranges from 3.3 to 14.5%, which may increase up to 19% in primary percutaneous coronary intervention (PCI) [1–3]. In ST-segment elevation myocardial infarction (STEMI) patients who are treated with primary PCI, AKI is associated with various ominous endpoints, including increased in-hospital and long-term morbidity and mortality [4–6]. Therefore, an early prediction, identification, and prevention of AKI is crucial for the management of these patients.

Pulse pressure (PP), which is associated with increased aortic stiffness, is obtained by subtracting diastolic blood pressure (DBP) from systolic blood pressure (SBP). It has been shown that increased aortic PP is independently associated with adverse cardiovascular events [7]. Since different combinations of SBP and DBP can give the same PP value, a new parameter of the pulsatile component of blood pressure has been developed to reflect arterial stiffness more directly than PP. Fractional PP (PPf), which is calculated as PP divided by the mean arterial pressure (MAP), theoretically cancels out the influence of cardiac output and peripheral vascular resistance, and it reflects arterial stiffness more directly than PP [8].

To date, various risk factors have been identified to be associated with the development of AKI, including pre-existing renal disease, diabetes mellitus, age, the type and volume of contrast agents, anemia, hypotension, intra-aortic balloon pump (IABP) use, left ventricular systolic dysfunction, and nephrotoxic drugs [9]. Increased arterial stiffness is related to a damaged kidney microvasculature, which may result in renal injury and end-stage renal disease [10]. In the present study, we aimed to evaluate the association between PPf and AKI in STEMI patients who underwent primary PCI.

Subjects and Methods

Study Population

This study was a retrospective analysis of 1,368 patients who were diagnosed with STEMI and underwent primary PCI between January 2013 and December 2018 in the cardiology departments of Kafkas University Hospital and Osmaniye State Hospital. After exclusion of patients with end-stage renal failure who were on hemodialysis or peritoneal dialysis (n = 18), or who were treated with emergent coronary artery bypass grafting surgery (n = 12) or who had a previous history of revascularization (n = 168), 1,170 patients were eligible for this analysis. Our hospital records indicated that all patients received medical treatment according to recent STEMI treatment guidelines. As per hospital protocol, all patients were intravenously hydrated with normal saline if they had no pulmonary edema or were not in cardiogenic shock. A low osmolar, non-ionic contrast media was used in all procedures.

Data Collection and Definitions

The patients’ detailed biochemical markers were measured on admission. In addition, hemoglobin and serum creatinine levels were tested daily. Cardiac biomarkers were obtained every 6 h until their peak levels and then daily. The Modification of Diet in Renal Disease Study Equation was used to calculate the estimated glomerular filtration rate (eGFR) from the serum creatinine level which was taken on admission. To assess renal dysfunction, serum creatinine levels of all patients were monitored during hospitalization. AKI was defined as either a 25% increase from baseline or a 0.5-mg/dL increase in absolute value within 48–72 h after the contrast media exposure. Detailed echocardiographic evaluations were performed within 24–48 h after the primary PCI, and the left ventricular ejection fraction (LVEF) was calculated using the modified Simpson’s technique.

The patients’ systolic, diastolic, and mean arterial blood pressure values, which were measured invasively after femoral or radial sheath insertion and before diagnostic coronary angiography, were obtained from the angiography documents and nursing care forms. The first measurement of 3–5 beats averaged after the calibration was taken. Hemodynamic parameters were calculated using the following formulae:

\[ PP = SBP - DBP \]

\[ PPf = PP / MAP \]

\[ \text{Pulsatility index} = PP / MAP \]

Angiographic Analysis

All patients underwent PCI via the radial or femoral approach. Prior to the intervention, all patients had been treated with acetylsalicylic acid, clopidogrel or ticagrelor, and unfractionated heparin at a dose of 70–100 U/kg. The decision on the use of IABP was made by the operator during or after the procedure. All procedures were performed with a non-ionic, low-osmolar contrast media. The procedure duration and the amount of contrast media used were retrieved from the patients’ angiography reports or hospital files. The patients’ angiography images, the synergy between PCI with taxus and cardiac surgery (SYNTAX) score, infract-related artery (IRA) characteristics, and the presence of chronic total occlusion were evaluated.

Statistical Analysis

SPSS statistical software version 21.0 (SPSS Inc., Chicago, IL, USA) was used to analyze the data. Continuous and categorical variables are presented as the mean ± SD and frequency and percentage, respectively. The distribution of continuous variables was evaluated by the Kolmogorov-Smirnov test. Variables with a normal distribution are presented as the mean ± SD. Those without a normal distribution are presented as the median (interquartile range). The Student t test or the Mann-Whitney U test were used to compare all continuous variables between the AKI and non-AKI groups. Either the χ² test or Fisher’s exact test was used to compare the categorical data. A two-tailed p value <0.05 was considered statistically significant. Univariable and multivariable logistic re-
gression analyses were performed to identify the independent predictors of AKI. To define the PPf value that predicted postcontrast AKI with the best specificity and sensitivity, receiver operating characteristic (ROC) curve analysis was used.

Results

In total, 1,170 consecutive STEMI patients were included in the study (mean age 56 years, 18.2% female). We observed that AKI occurred in 143 (12.2%) patients. The study cohort was classified into 2 groups: patients with AKI and those without it. Hemodialysis was required in 6.3% (n = 9) of AKI patients. The AKI group was older and composed of more female patients. The frequencies of hypertension and diabetes mellitus were higher and LVEF and eGFR levels were lower in the AKI group than those without AKI. In terms of laboratory parameters, hemoglobin levels were lower, but plasma glucose, C-reactive protein (CRP), creatinine, and troponin levels were higher in AKI patients (Table 1).

Although there was no significant difference between the 2 groups in terms of SBP, MAP, and PP values, DBP values were lower in patients with AKI. PPf and pulsatility index values were significantly higher in AKI patients (0.53 ± 0.10 vs. 0.61 ± 0.10, p < 0.001, and 0.80 ± 0.03 vs. 0.82 ± 0.03, p < 0.001, respectively). The frequency of hypotension, cardiogenic shock, Killip class >1, and the use of IABP were higher in patients with AKI compared to those without AKI (48 [4.7%] vs. 39 [27.3%], 25 [2.4%] vs. 26 [18.2%], 137 [13.3%] vs. 55 [38.5%], and 35 [3.4%] vs. 31 [21.7%], respectively, p < 0.001 in each case). The SYN-TAX scores and the presence of chronic total occlusion were higher in patients with AKI. Moreover, total ischemic time was longer in patients with AKI than those without AKI (225 min [range 138–325] vs. 167 min [range 110–252], p < 0.001). The volume of contrast agent used during revascularization procedures was higher in the AKI group (338 ± 91 vs. 261 ± 63 mL, p < 0.001). The in-hospital mortality rate was significantly higher in patients with AKI than those without it (27 [18.8%] vs. 12 [1.2%), p < 0.001). All patients’ clinical and angiographic characteristics are detailed in Table 2.

To identify the independent predictors of AKI, multivariable logistic regression analyses were performed using the variables that showed marginal association with AKI in univariable analyses. Among these variables, age (per 1 year), hemoglobin (per 1 g/dL), contrast volume (per 1 mL), CRP (per 1 mg/dL), and PPf ×10 were taken as continuous variables. Age, hemoglobin, proximal/ostial lesions for IRA, hypotension, contrast volume, CRP, and PPf were found to be related with AKI in univariable and multivariable analysis (Table 3). After exclusion of the patients with cardiogenic shock/hypotension, there was no major change in the results of multivariable logistic regression analyses in

predicting AKI (Table 4). In the ROC analysis, the best cut-off value of the PPf was 0.52 with a sensitivity of 83.2% and a specificity of 50.3%. The area under the curve (AUC) value for PPf (AUC 0.722; 95% CI 0.695–0.748) was significantly higher than AUC for SPB (AUC 0.517; 95% CI 0.488–0.546), DPB (AUC 0.576; 95% CI 0.547–0.605), MAP (AUC 0.547; 95% CI 0.518–0.576), pulsatility index (AUC 0.683; 95% CI 0.625–0.710), and PP (AUC 0.541; 95% CI 0.512–0.570; p < 0.005 for each; Fig. 1).

Even if not optimal, when we reclassified using the criteria of the Acute Kidney Injury Network (AKIN) other than urine output, we diagnosed AKI in 129 patients, and found that we did not underestimate those patients. We compared our definition with AKIN definition, and we found 99.2% consistency.

| PPf ×10                | <0.001    | 2.183 (1.823–2.614)    | <0.001     | 1.874 (1.513–2.322)    |

All clinically relevant parameters were included in the model. AKI, acute kidney injury; IRA, infarct related artery; CRP, C-reactive protein; PPf, fractional pulse pressure.
In the present study, we investigated whether PPf was associated with AKI in patients with STEMI who underwent primary PCI. The main finding of our study is that invasively measured PPf is associated with AKI. In addition, PPf may be an independent predictor of AKI in patients with STEMI who underwent primary PCI. To the best of our knowledge, there is no such data in the literature.

**Discussion**

In the present study, we investigated whether PPf was associated with AKI in patients with STEMI who underwent primary PCI. The main finding of our study is that invasively measured PPf is associated with AKI. In addition, PPf may be an independent predictor of AKI in patients with STEMI who underwent primary PCI. To the best of our knowledge, there is no such data in the literature.
Primary PCI is a vitally important standard treatment option for STEMI patients. However, AKI is a major disadvantage for patients who are treated with primary PCI. AKI is associated with a longer hospital stay, additional cost, and increased in-hospital and long-term morbidity and mortality [4–6]. The incidence of AKI in patients undergoing emergency PCI due to acute coronary syndrome does not appear to be low, with rates ranging from 13.3 to 28% [5, 11, 12]. Compared to previous studies, the frequency of AKI in this study was 12.2%, which appeared to be lower. Despite the fact that relatively high rates have been reported in some publications (11%) [13], when the AKI rates in patients undergoing contrast-enhanced computed tomography are analyzed, the rates of the contrast-induced nephropathy after imaging in the more comprehensive meta-analysis are around 6%, which is lower than the AKI rates seen in STEMI patients [14]. The reasons for a higher incidence of renal impairment observed in STEMI patients may be related not only to the use of contrast agent, but also different hemodynamic and inflammatory variables may be present. Hence, AKI in STEMI patients differs from contrast-induced nephropathy in patients during imaging [13]. To date, several AKI risk factors have been identified such as baseline renal impairment, hypotension, congestive heart failure, diabetes mellitus, advanced age, and anemia [2, 11, 15, 16]. Consistent with prior studies, in this study, AKI patients were older, had lower baseline eGFR, LVEF, and hemoglobin levels, but had higher levels of creatinine and troponin. Hypertension and diabetes mellitus were more frequent in patients with AKI than those without AKI.

Ischemic injury and myocardial necrosis due to STEMI trigger an acute inflammatory process, and an elevated CRP level has been found to be related with AKI development in STEMI patients [17]. During the inflammatory process, increased CRP activates the coagulation system, leads to an increase in the secretion of adhesion molecules, and reduces nitric oxide production [18]. Endothelial dysfunction and decreased renal vasodilator activity have been shown to contribute to AKI development [19]. Consistent with the literature, in this study, CRP was found to be an independent predictor of AKI development. Additionally, in our study, white blood cell counts and glucose levels were higher in AKI patients than those without.

Baseline renal dysfunction and hemodynamic deterioration have a great effect on AKI development, as demonstrated by the Bremen registry study, in which the researchers investigated AKI predictors in STEMI patients. Based on this study finding, many parameters have been used in many risk classifications [5, 11, 15]. Hemodynamic impairment may precipitate reduction in renal blood flow and lead to activation of the renin-angiotensin-aldosterone and sympathetic systems. All of these changes can ultimately lead to renal vasoconstriction and renal medullary hypoxia, resulting in AKI development. Because of the longer duration of the renal elimination of contrast media and prolonged exposure to the toxic agents, AKI rates are higher in patients with initial renal dysfunction [20]. Evaluating the current study results from this perspective, the frequency of hypotension, shock, Killip class >1, and the use of IABP, all of which are consequences of a deteriorated hemodynamic status, were higher in patients with AKI than those without, which is in line with the current literature. Peripheral arterial disease was also significantly associated with major adverse cardiac events in acute coronary syndrome patients [21]. Higher SYNTAX scores have been correlated with AKI development, more adverse cardiac events, and the need for hemodialysis in patients with acute coronary syndrome [22, 23]. In parallel with the literature, in the current study, the SYNTAX score was higher in patients with AKI than those without. Additionally, the rate of proximal/ostial lesions for IRA and the presence of chronic total occlusion was higher in patients with AKI. We considered that the underlying reasons may be the longer procedure duration, the use of a higher contrast media volume, and greater ischemic myocardial volume.

PP, which is the difference between SBP and DBP, reflects aortic stiffness [24]. As stiffening of the central elastic vessels causes greater reflected waves in the early systole, it increases PP in general. Large cohort studies have demonstrated the relationship between PP and adverse cardiovascular events [7, 25]. However, Mahfouz et al. [8] showed that PPf is superior to PP in predicting aortic stiffness. Their hypothesis was that dividing the PP by MAP excludes the impact of cardiac output and peripheral vascular resistance. As renal microvascular resistance is very low and the kidneys are perfused at high-flow volume throughout the systole and diastole, it has been suggested that excessive pulsatile energy transmission into the susceptible renal microvasculature causes progression of kidney damage [26]. In other studies, acceleration in aortic stiffening is related with renal function deterioration [27, 28]. However, evaluating aortic stiffness can be difficult and time-consuming in STEMI patients before a PCI procedure. We hypothesized that increased PPf, which is associated with aortic stiffness, could be associated with AKI. In addition to the known risk factors, we found that PPf was also an independent predictor of AKI in STEMI patients. We considered that both low
MAP and high PP have a significant effect on renal impairment in STEMI patients undergoing primary PCI. Therefore, PPf, by combining both of these, may be a valid independent predictor of AKI.

Some limitations should be noted regarding the present study. It had a retrospective design and only in-hospital data were available. Therefore, no inferences on long-term results could be made. We did not have urine outputs of all patients, so we could not use the RIFLE (risk, injury, failure, loss of kidney function, and end-stage kidney disease) or the AKIN classifications [29, 30]. Since the endpoint of the study was AKI, other adverse events were not evaluated. Although well-known risk factors have been evaluated in the study, some residual unmeasured confounders might have affected our results. Due to the retrospective nature of the study, the arterial stiffness indices were absent and could not be investigated in relation to PPf.

**Conclusion**

The present study demonstrates that PPf is an independent predictor of AKI in STEMI patients treated with primary PCI. In addition, PPf is superior to other blood pressure values and derivatives in AKI prediction. Based on our results, the use of PPf in AKI prediction may play an important role in the management of these patients.

**Statement of Ethics**

The Kafkas University Ethics Committee reviewed and approved the current study protocol in accordance with the principles of the Declaration of Helsinki.

**Conflict of Interest Statement**

The authors have no conflicts of interest to declare. This research did not receive any specific grant from funding agencies in the public, commercial, or not-for-profit sectors.
