Event-by-event $\gamma$–ch correlation is used in studying systems going through QCD chiral phase transition. In this paper various methods for measuring $\gamma$–ch correlation in heavy ion collisions have been discussed. Dynamical fluctuation due to formation of domains of DCC that can affect $\gamma$–ch correlation has been discussed. We study known detector and statistical effects involved in these measurements and suggest suitable robust observables $\Delta_\nu_{dyn}$ and $r_{m,1}$ sensitive to small $\gamma$–ch correlation signal. These variables are constructed based on moments of multiplicity distributions of photon and charged particles. Estimations of expected measurable signals of $\gamma$–ch correlation from various available models such as for ideal Boltzmann gas of pions, monte-carlo models based on transport and mini-jets have been discussed. Collision centrality dependence of the observables have been estimated from Central Limit Theorem and found to be consistent with the model predictions. We find that observables show high sensitivity to fraction of DCC events and have nonlinear dependence on fraction of pions carrying DCC signals. Variation of $r_{m,1}$ with orders of its higher moments $m$ is a observable to extract the nature and strength of $\gamma$–ch correlation.

I. INTRODUCTION

Based on decades of experimental searches and theoretical studies it is widely believed that high energy heavy ion collisions produce realistic scenario for studying the phase transition from hadronic matter to quark gluon plasma. It is believed to be associated with two different transitions, de-confinement and restoration of QCD chiral symmetry. Fluctuation of conserved quantities has been proposed [1] to be an important experimental signature for such phase transition. Hadronic system that is mostly dominated by pions is expected to show a global isospin conservation. In such scenario the event-by-event isospin number fluctuation is an interesting observable. The QCD chiral phase transition is associated with melting of 4-vector condensates. An interesting phenomena like formation of metastable domains of “Disoriented Chiral Condensate” (DCC) is predicted to occur due to the orientation of this condensate relative to the direction of its scalar component. Such a phenomena is possible for a scenario of rapid cooling like quenching [2,3] for system going from chiral symmetry restored phase to broken phase. Formation of DCC domains causes anomalous production of charged or neutral pions depending on the orientation of vacuum towards its pseudo scalar component. Such phenomena might survive final state interactions and appear in the form of multiplicity fluctuation of pions of relative isospins [4]. As the detected charged and neutral particles are mostly from the charged pions and the decay of neutral pions respectively this would appear in the form of $\gamma$–ch anti-correlation. The experimental searches of DCC so far includes searches in pp collisions [5], cosmic ray events [6] and in heavy ion collisions [7,12]. Our discussion would be relevant to the search in heavy-ion collisions. The prediction for a hot medium described by the linear sigma model [13] showed that in the case of central collision of Pb-Pb at SPS energies, the likelihood of the DCC events is less than $10^{-3}$. Experimental searches at SPS WA98 experiment [5,11] at $\sqrt{s} = 17.3$ GeV estimated an upper limit of $3 \times 10^{-3}$. It has been argued [14] that in case of rapid cooling like quenching scenario, higher collision energies corresponding to lower chemical potential (e.g. $\mu_{RHIC} < \mu_{SPS}$) provides faster cooling rate ($|dT/dt|$). This suggests that RHIC and LHC collisions provide more favorable condition for DCC production than SPS collisions.

From experimental point of view such a study is associated with simultaneous measurement of photons and charged particles in common phase space with very high sensitivity at low momentum. This is because the decay of domains of DCC are final stage phenomena of the evolution of heavy ion collision and the pions carrying signals are expected to be of low momentum. A combination of pre-shower Photon Multiplicity detector (PMD) [15] and forward time projection chamber (FTPC) [16] at STAR experiment at RHIC and Photon Multiplicity detector (PMD) and Forward Multiplicity Detector (FMD) at ALICE experiment [17] at LHC have the required criteria to satisfy such goal.

In this paper we would like to highlight few issues associated to $\gamma$–ch correlation analysis and propose a method. We use generating function approach to calculate different variables and include various detection effects like efficiencies, effect of mis-identification etc. Observables of $\gamma$–ch correlation are constructed to be suitable for heavy ion collisions that can disentangle dynamical fluctuation. Assuming formation of DCC domains to be one of the probable sources of dynamical signal of isospin fluctuation we discuss the sensitivity of the observables to the fraction of DCC events and the fraction of DCC candidates in an event. Relevant to the heavy ion collisions we discuss the centrality dependance of the variables. We estimate $\gamma$–ch correlation from various models and implement a DCC-model based on HIJING event generator.

In the section II we outline the method of construction of the observables and their values for DCC events of varying fraction. Section III, IV and V describe the de-
ector effect like mis-identification, the role of resonances and centrality dependence respectively on the proposed variables. In section \[ \text{VI} \] we have calculated the sensitivity of the variables on DCC event fraction and pion fractions in DCC events. For studying the experimental sensitivity of DCC, we have studied various non-DCC models in section \[ \text{VII} \] and implemented DCC in a Monte-Carlo based events in section \[ \text{VIII} \]. We summarize in section \[ \text{IX} \].

II. METHOD

Fluctuation of particle ratios has been addressed previously in case of conserved quantities like net strangeness in terms of kaon-to-pion ratio and net baryons in terms of proton to pion ratios. Relevant to our case is the study of photon to charge particle multiplicity ratio. Observables used in such cases are designed in such a way so as to eliminate the statistical fluctuations and at the same time be robust against detector inefficiency. A simple way of implementing detector efficiencies in terms of a binomial probability distribution function say of the form \( P(n, N, \varepsilon) = \binom{N}{n} \varepsilon^n (1 - \varepsilon)^{N-n} \) would reveal the fact that the second moment of observed multiplicity \( n \) is not proportional to second moment of produced multiplicity \( N \). The efficiency term \( \varepsilon \) does not factorize for quantities like variance, skewness and kurtosis\(^1\). However the quantities like observed second and higher order factorial moments come out to be proportional to the measured corresponding factorial moments like \( \langle n(n-1) \rangle = \varepsilon^2 \langle (N(N-1)) \rangle \). Ratios of various factorial moments with powers of mean multiplicity could simply cancel the explicit efficiency dependence. In case of correlation of multiplicities, there could be more complicated detector effects like mis-identification of one species in the form of another, decay and resonance production. This could lead to spurious correlation affecting the final results. Also in case of heavy ion collisions there are centrality and system size dependence. If heavy-ion collisions are assumed to be linear superpositions of multiple hadronic collisions, then variables are supposed to show number of source scaling \[ \text{22} \]. Based on similar context and considering various other aspects of particle ratio-fluctuation, two observables were introduced earlier as measure of \( \gamma - ch \)-ratio fluctuations. \( \nu_{\gamma - ch}^{\text{dyn}} \) was introduced in Ref \[ \text{18} \] and used by STAR Collaboration \[ \text{16} \ [ \text{20} \] and \( r_{m,1}^{\gamma - ch} \) was introduced by Minimax collaboration \[ \text{21} \]. The variable \( \nu_{\gamma - ch}^{\text{dyn}} \) is defined as

\[
\nu_{\gamma - ch}^{\text{dyn}} = \frac{\langle N_{\gamma} (N_{\gamma} - 1) \rangle}{\langle N_{\gamma} \rangle^2} + \frac{\langle N_{\gamma} (N_{\gamma} - 1) \rangle}{\langle N_{\gamma} \rangle^2} - 2 \frac{\langle N_{\gamma} \rangle}{\langle N_{\gamma} \rangle} \frac{\langle N_{\gamma} \rangle}{\langle N_{\gamma} \rangle}
\]

(1)

which for Poissonian case should give zero. The variable \( r_{m,1}^{\gamma - ch} \) is defined as

\[
r_{m,1}^{\gamma - ch} = \frac{\langle N_{ch} (N_{ch} - 1) \rangle}{\langle N_{ch} (N_{ch} - 1) \rangle} - \frac{\langle N_{ch} (N_{ch} - 1) \rangle}{\langle N_{ch} (N_{ch} - 1) \rangle} \frac{\langle N_{ch} (N_{ch} - 1) \rangle}{\langle N_{ch} (N_{ch} - 1) \rangle}
\]

(2)

It is designed such that for all the moments it gives a value equal to 1 for Poisson case and higher order moments show larger sensitivity to signals. In this section we would like to discuss the applicability, robustness and sensitivity of these two variable for \( \gamma - ch \) correlation. Since we are interested in fluctuation of ratio of multiplicities let us consider \( f = N_{\pi^0} / (N_{\pi^0} + N_{\pi^+}) \) to be the neutral pion fraction. The idea is that by using proper combinations of moments we can eliminate the efficiency dependence and express our observable in terms of the fluctuation of the fraction \( f \). The most efficient way of studying the moments including the dynamical and detector effect is to follow the generating function approach \[ \text{21} \] where we define,

\[
G(z) = \sum_{N=0}^{\infty} z^N P(N)
\]

(3)

where \( P(N) \) denotes the distribution of parent multiplicity where \( N = N_0 + N_{ch} \) denotes sum of all neutral and charged pions. Different moments are calculated by taking derivatives of \( G(z) \) w.r.t \( z \) evaluated at \( z = 1 \). Considering the fact that the neutral pions are distributed according to the probability \( P(f) \) the generating function has to be modified accordingly

\[
G(z_{ch}, z_0) = \int_0^1 df \frac{\sum_{N} P(N) [f z_0 + (1 - f) z_{ch}]}{\sum_{N} P(N) [f z_0 + (1 - f) z_{ch}]}^N.
\]

(4)

The distribution \( P(f) \) is the event-by-event measured distribution of neutral pion fraction. Isospin symmetry for a pion gas corresponds to a generic case of pion productions for which \( P(f) = \delta(f - 1/3) \). In case of DCC like events \[ \text{3} \ [ \text{4} \] we have \( P(f) = 1/2\sqrt{f} \). For propagation of generating function to include the decay of neutral pions to observed photons we apply the “cluster decay theorem” \[ \text{22} \]. We can express the overall generating function as

\[
G_{\text{obs}} (z_{ch}, z_0) = G (g_{ch} (z_{ch}), g_0 (z_0))
\]

(5)

where \( g_0 (z_0) = z_0^2 \) considering the fact that every neutral cluster decays into two photons and the charge particles do not decay, \( g_{ch} (z_{ch}) = z_{ch} \). To make the scenario more realistic and taking the advantage of same theorem, one can include detection efficiencies into the final form of

\[ \text{variable } D = 4 \langle \Delta Q^2 \rangle / N_{ch} \text{, where } Q^2 \text{ is the variance of the net charge(} N_+ - N_- \text{)} \text{ in Ref.} \]

\[ \text{ gives different values for QGP and pion gas but depends on efficiency.} \]

\[ \text{1} \]
generating function. We consider the observing and non-observing as different decay modes with probability equal to the detection efficiency. So for charged and neutral clusters we redefine

\[ g_{\text{ch}}(z_{\text{ch}}) = (1 - \varepsilon_{\text{ch}}) + \varepsilon_{\text{ch}} z_{\text{ch}} \]

Here \( \varepsilon_{\text{ch}} \) is the efficiency of charge particle detection and \( \varepsilon_{\gamma} \) is the efficiency of detecting a photon coming from decay of a neutral pion. We can calculate various factorial moments of multiplicity with detector efficiency folded in terms of derivatives of final generating function. We can define a generalized factorial moment as

\[ f_{m,n} = \frac{\partial^{m,n} G_{\text{obs}}(z_{\text{ch}}, z_{\gamma})}{\partial z_{\text{ch}}^m \partial z_{\gamma}^n} \bigg|_{z_{\text{ch}} = z_{\gamma} = 1} \left( \frac{N_{\text{ch}}! N_{\gamma}!}{(N_{\text{ch}} - m)! (N_{\gamma} - n)!} \right) \]

It is convenient to express our observables given in eq.4 and eq.2 in terms \( f_{m,n} \) as

\[ \nu_{\text{dyn}}^{\gamma-\text{ch}} = \frac{f_{20}}{f_{02}} + \frac{f_{02}}{f_{01}} 2 \frac{f_{11}}{f_{10} f_{01}}, \quad r_{m,1}^{\gamma-\text{ch}} = \frac{f_{10} f_{10}}{f_{(m+1)0} f_{01}} \]

Using eq.4, eq.5 and eq.7 we can express few factorial moments in terms efficiency and average of neutral pion fraction

\[ f_{10} = \langle 1 - f \rangle \varepsilon_{\text{ch}} \langle N \rangle 
\]

\[ f_{01} = \langle f \rangle 2 \varepsilon_{\gamma} \langle N \rangle 
\]

\[ f_{11} = \langle f (1 - f) \rangle 2 \varepsilon_{\text{ch}} \varepsilon_{\gamma} \langle N (N - 1) \rangle 
\]

\[ f_{20} = \langle (1 - f)^2 \rangle \varepsilon_{\text{ch}}^2 \langle N (N - 1) \rangle 
\]

\[ f_{02} = \langle f^2 \rangle 4 \varepsilon_{\gamma}^2 \langle N (N - 1) \rangle + 2 \varepsilon_{\text{ch}}^2 \langle N \rangle \]

Substituting these in eq.11 we obtain

\[ \nu_{\text{dyn}}^{\gamma-\text{ch}} = \left( \frac{\langle (1 - f)^2 \rangle}{(1 - f)^2} + \frac{\langle f^2 \rangle}{(f)^2} - 2 \frac{\langle f (1 - f) \rangle}{(f) (1 - f)} \right) \frac{\langle N (N - 1) \rangle}{(N)^2} \]

\[ + \frac{1}{\langle f \rangle (N)} \]

We note here that the for generic case the term inside the bracket is zero and we have

\[ \nu_{\text{dyn}}^{\gamma-\text{ch}}_{\text{generic}} = \frac{1}{\langle f \rangle} \frac{\langle N (N - 1) \rangle}{(N)^2} \]

Using proper combination of factorial moments and doing a simple method of event mixing one can extract the generic value of \( \nu_{\text{dyn}}^{\gamma-\text{ch}} \) (see appendix A for details).

Subtracting the generic value of \( \nu_{\text{dyn}}^{\gamma-\text{ch}} \) one can get rid of the last term in eq.11

So we propose a modified variable \( \nu_{\text{dyn}} - \nu_{\text{dyn}}^{\gamma-\text{ch}} \) given by

\[ \Delta \nu_{\text{dyn}}^{\gamma-\text{ch}} = \left( \frac{\langle (1 - f)^2 \rangle}{(1 - f)^2} + \frac{\langle f^2 \rangle}{(f)^2} - 2 \frac{\langle f (1 - f) \rangle}{(f) (1 - f)} \right) \frac{\langle N (N - 1) \rangle}{(N)^2} \]

In ideal scenarios when all the particles are detected one can approximate \( g_0(z_{\gamma}) = z_{\gamma}^2 \) and \( g_{\text{ch}}(z_{\text{ch}}) = z_{\text{ch}} \). In that case one can show using eq.5 and eq.7 that

\[ \nu_{\text{dyn}}^{\gamma-\text{ch}}_{\text{generic}} = \frac{1}{2 \langle N \rangle} \frac{\langle f \rangle}{(f)} \approx \frac{1}{\sqrt{\langle N_{\text{ch}} \rangle} \langle N_{\gamma} \rangle} \]

irrespective of any value of \( \nu_{\text{dyn}} \). So in that case the observable \( \Delta \nu_{\text{dyn}}^{\gamma-\text{ch}} \) can be estimated to be

\[ \Delta \nu_{\text{dyn}}^{\gamma-\text{ch}} = \nu_{\text{dyn}}^{\gamma-\text{ch}} - \frac{1}{\sqrt{\langle N_{\text{ch}} \rangle} \langle N_{\gamma} \rangle} \]

Following the same approach one can express the variable \( r_{m,1} \) as

\[ r_{m,1}^{\gamma-\text{ch}} = \frac{\langle f (1 - f)^m \rangle}{\langle f \rangle} \frac{\langle 1 - f \rangle}{\langle f \rangle} \]

Now we would like to discuss the sensitivity of these two variables for a given fraction of DCC like signal. If x-fraction of events has DCC like domain formation, in simplistic case one can assume that the distribution of neutral pion fraction to be a combination of generic and DCC probability distribution given by

\[ P(f) = \frac{1}{2\sqrt{f}} + (1 - x) \delta \left( f - \frac{1}{3} \right) \]

So for \( \Delta \nu_{\text{dyn}} \) we have from eq.11

\[ \Delta \nu_{\text{dyn}}^{\gamma-\text{ch}} = \left( \frac{\langle (1 - f)^2 \rangle}{(1 - f)^2} + \frac{\langle f^2 \rangle}{(f)^2} - 2 \frac{\langle f (1 - f) \rangle}{(f) (1 - f)} \right) \frac{\langle N (N - 1) \rangle}{\langle f \rangle \langle N \rangle} \]

\[ \times \frac{\langle N (N - 1) \rangle}{\langle f \rangle \langle N \rangle} \]

which is proportional to the fraction of DCC-like events. \( \Delta \nu_{\text{dyn}} \) shows very high sensitivity to DCC like signal but it has dependency on the parent multiplicity and consequently to the collisions centrality. In later section we would discuss this issue in detail. In case parent distribution is Poissonian, the fluctuation term \( \langle N (N - 1) \rangle / \langle N \rangle^2 \) would be equal to 1 giving \( \Delta \nu_{\text{dyn}}^{\gamma-\text{ch}} \sim x/(5/9) \).

The robust observable expressed in eq.14 would have a very particular \( x \) dependence given by

\[ r_{m,1}^{\gamma-\text{ch}} = 1 - \frac{m x}{(m + 1)} F(m, x) \]

where the function \( F(m, x) \) is given by

\[ F(m, x) = \frac{1}{x + (1 - x) \frac{2}{\sqrt{m}} (\frac{2}{3})^{m+1} \frac{\Gamma(m+5/2)}{\Gamma(m+2)}} \]

For ideal DCC case \( x=1 \), the function \( F(m, x)=1 \) for all values of \( m \). That gives \( r_{m,1} = 1/(m+1) \). For generic
case \((x = 0)\), \(r_{m,1} = 1\). Fig. 1 shows the sensitivity of \(r_{m,1}\) for small signals of DCC. The functional form given in eq. 17 can be used to extract \(x\) from a fit of \(r_{m,1}\) with \(m\). In the derivation of eq. 16 and eq. 17 we have assumed that the parent multiplicity distribution are similar for both the generic and DCC case and the efficiency factors are constant and independent of multiplicity and other kinematic parameters.

### III. EFFECT OF MIS-IDENTIFICATION

There are additional complications in realistic scenarios that have not been taken care of in the above prescriptions. The study of \(\gamma - ch\) correlation is often complicated by mis-identification of charge particles by photons and vice versa. High energy deposits of charged hadrons can form a cluster in photon detector. Similarly photon conversion can show up as single or doubly detected tracks or clusters in charge particle detectors. In both the cases the observables are affected. Following the approach of the application of cluster decay theorem discussed in previous section, we obtain the modified forms of the generating functions

\[
\begin{align*}
g_{ch}(\varepsilon_{ch} z_{\gamma}) &= (1 - \varepsilon_{ch} z_{\gamma}) + \varepsilon_{ch} z_{\gamma} + \varepsilon_{ch} \varepsilon_{\gamma} z_{\gamma} \\
g_{0}(\varepsilon_{ch} z_{\gamma}) &= ((1 - \varepsilon_{ch} \varepsilon_{\gamma} z_{\gamma}) + \varepsilon_{\gamma} z_{\gamma} \\
&+ \varepsilon_{\gamma} z_{\gamma}^{2} + \varepsilon_{\gamma}^{2} z_{\gamma}^{2})^2, \quad (19)
\end{align*}
\]

where the the generic value of \(\nu_{dyn}\) in this case will be given by

\[
\nu_{dyn}^{-ch} \bigg|_{generic} = \frac{1}{2 \langle f \rangle \langle N \rangle (\frac{\varepsilon_{ch}}{\varepsilon_{\gamma}} + 1)} \quad (22)
\]

which is small number for large values of \(\langle N \rangle\). The robust variable \(r_{m,1}\) can be represented as

\[
r_{m,1}^{-ch} = \frac{\langle (1 - f)^m \left(1 - f \frac{\varepsilon_{ch}}{\varepsilon_{\gamma}} + 2f \right) \rangle \langle 1 - f \rangle}{\langle (1 - f)^{m+1} \left(1 - f \frac{\varepsilon_{ch}}{\varepsilon_{\gamma}} + 2f \right) \rangle}, \quad (23)
\]

Unlike previous case it is not possible to eliminate the efficiency factors in eq. 21 and eq. 23. So in this case if we want to analyze the sensitivity of those variables to \(x\)-fraction of DCC signals, we can use eq. 16 to obtain the modified forms as

\[
\Delta \nu_{dyn}^{-ch} = \frac{x}{5/9} \left(\frac{\varepsilon_{ch}}{\varepsilon_{\gamma}} + 1\right)^2 \langle N(N-1) \rangle \langle N \rangle^{-2} \\
r_{m,1} = 1 - \frac{mX}{m+1} \left(\frac{\varepsilon_{ch}}{\varepsilon_{\gamma}} + 1\right) F(m, x). \quad (24)
\]

where \(F(m, x)\) is given by eq. 18. We can see that mis identification of charged particle as photon reduces the effective fraction of DCC events. The contamination factor appears as a ratio of \(\varepsilon_{ch} / \varepsilon_{\gamma}\) keeping the functional form of the variables (eq. 16 \(\varepsilon_{ch} / \varepsilon_{\gamma}\) unchanged. We note here that \(\Delta \nu_{dyn}^{-ch}\) has quadratic dependence on contamination factor whereas \(r_{1,1}\) is affected only by a linear factor. This is because \(\Delta \nu_{dyn}^{-ch}\) contains an extra photon fluctuation term absent in \(r_{m,1}\).
IV. RESONANCE EFFECT

Resonance decays like $\rho \to \pi^{\pm} \gamma$ is equivalent to artificial increase of pions and photons from generic case. Decays like $\omega \to \pi^{0} + \pi^{\pm}$ would give rise to correlation in the pions. Overall effect of resonance would be equivalent to event-by-event fluctuation of charged or neutral particles. The effect of resonance leading to increase in photon and charged particle multiplicity could be considered to be equivalent to increase in efficiency of photon and charged particle detection. For event-by-event fluctuations of efficiency would affect the observables, for e.g. the variable $r_{m,1}$ given in eq.(13) will be modified as

$$r_{m,1}^{\gamma-ch} = \frac{\langle f (1-f)^m \rangle \langle 1-f \rangle \langle \epsilon_{\gamma} \epsilon_{ch} \rangle \langle \epsilon_{ch} \rangle}{\langle (1-f)^{m+1} \rangle \langle f \rangle \langle \epsilon_{ch}^{m+1} \rangle \langle \epsilon_{\gamma} \rangle}$$

(25)

It is difficult to conclude the behavior of the variables from the above expressions without putting a realistic number for the efficiencies. To study the effect of resonances in a more detailed way (see VIII VII we have used Monte-Carlo models in which resonances are included.

V. CENTRALITY DEPENDENCE

In heavy ion collisions, signals are expected to have centrality dependence, it is therefore important to study the centrality dependence of the $\gamma-ch$ correlation. In a heavy ion collision, let us consider $N_S$ numbers of identical sources are responsible for particle production. If $N_i$ is the number of particles produced from $i$-th source, any variable $V(N_i)$ will have a distribution identical for all the sources. If we assume heavy-ion collision to be a linear superposition of many identical nucleon-nucleon collisions, under identical source approximation we can calculate the centrality dependence of the variable using “central limit theorem” (CLT) [23]. From CLT it follows that mean and variance of multiplicity would be given by

$$M(N) = M \left( \sum_{i} N_i \right) = \sum_{i} M(N_i) = N_S M(N_i)$$

$$\sigma^2(N) = \sigma^2 \left( \sum_{i} N_i \right) = \sum_{i} \sigma^2(N_i) = N_S \sigma^2(N_i).$$

(26)

So from CLT we have the dependence $M(N) = \alpha N_S$ and $\sigma(N) = \beta \sqrt{N_S}$. Let us assume $N$ to be equal to the total number of produced pions where we have $N_{\pi} = a N_{ch} + b N_{\gamma}$. $N$ could also refer to individual number of photons or charged particles. In that case similar argument also holds for $M(N_{ch}) \sim \alpha_1 N_S$ and $M(N_{\gamma}) \sim \alpha_2 N_S$. The variance of total numbers of pions would give

$$\sigma^2(N_{\pi}) = \langle N_{\pi}^2 \rangle - \langle N_{\pi} \rangle^2 \sim \beta^2 N_S$$

$$\langle N_{\pi}^2 \rangle = \langle (a N_{ch} + b N_{\gamma})^2 \rangle \sim \beta_1 N_S + \beta_2 N_S^2$$

(27)

(28)

and if we express pion multiplicity in terms of charged and photons we get,

$$\langle N_{ch}^2 \rangle \propto \beta_1 N_S + \beta_2 N_S^2$$

$$\langle N_{ch}^2 \rangle \propto \beta_1 N_S + \beta_2 N_S^2$$

$$\langle N_{ch} N_{\gamma} \rangle \propto \beta_1 N_S + \beta_2 N_S^2$$

(29)
So from eq.11 and eq.12 we can calculate the centrality dependence of the observables. For \( \nu_{\text{dyn}} \) one has

\[
\nu_{\text{dyn}}^{\gamma_{\text{ch}}} \sim A + \frac{B}{N_S} \equiv A' + \frac{B'}{\sqrt{\langle N_{\gamma} \rangle \langle N_{\text{ch}} \rangle}} \tag{30}
\]

which is in fact the centrality dependence of all three terms in eq.11. Here we note that the constants \( A' \) and \( B' \) could be either positive or negative depending on which term in eq.11 is dominant. The variable \( \Delta \nu_{\text{dyn}} \) would have the similar centrality dependence which is obvious from the form of eq.13. In heavy ion collisions, number of source participating in particle production can also be placed by \( B' \). In heavy ion data. There are theoretical predictions of isospin fluctuation for a statistical system of pions. In this case the generating function of eq.4 will be replaced by

\[
G_{\text{obs}} = x' G_{\text{DCC}} + x G_{\text{DCC}} G_{\text{generic}} + (1-x-x')G_{\text{generic}} \tag{32}
\]

in which we view cases with 100% DCC production (\( x' \) fraction of events), 100% generic production and a mixture of two as three “decay modes” of a super cluster. Here \( G_{\text{DCC}} \) has the probability distribution \( P(f) = 1/2\sqrt{f} \) and \( G_{\text{generic}} \) has \( P(f) = \delta(f - 1/3) \). Since we think the case of 100% DCC production is the least realistic, in the following we simplify our expression by taking \( x' = 0 \). Now different factorial moments will become functions of \( x \) and \( y \) (see appendix-X C for detail). In this case the observables are modified accordingly, for \( \Delta \nu_{\text{dyn}} \) from eq.13 will be given by

\[
\Delta \nu_{\text{dyn}} = x \frac{5}{9} y^2 \frac{(N(N-1))}{\langle N \rangle^2} \tag{33}
\]

which consistent with the expression eq.16 for \( y = 1 \) case. For Poisson like parent distribution \( \Delta \nu_{\text{dyn}} \) can be expressed as

\[
\Delta \nu_{\text{dyn}} = x \frac{5}{9} y^2. \tag{34}
\]

We note here that \( \Delta \nu_{\text{dyn}} \) still shows the proportionality with the fraction of DCC events \( x \). And the interesting fact is that quadratic dependance on \( y \) means \( \Delta \nu_{\text{dyn}} \) is more sensitive to the change of fraction of pions carrying DCC-like signals.

In similar approach we can express \( r_{1,1} \) to be

\[
r_{1,1} = \frac{5 - 2xy^2}{5 + xy^2}. \tag{35}
\]

This expression is consistent with the approximate expression of \( r_{1,1} \) given in Ref.23 for small values of \( x \). The higher order moments will have corrections from higher orders of \( y \) which are smaller. To the lowest order approximation, the expression given by eq.17 is still valid with fraction \( x \) replaced by \( xy^2 \).

\[
r_{m,1}^{\gamma_{\text{ch}}} \approx 1 - \frac{mxy^2}{(m+1)} F(m, xy^2) \tag{36}
\]

A functional fit of \( r_{m,1} \) with \( m \) to experimental data by the above expression can restrict the contours of \( x \) and \( y \).

VI. EFFECT OF MIXTURE OF PION SOURCES

In this section we would like to discuss the effect on the observables when event wise pion sources are independent of each other. So far we have considered that in a DCC event, all the pions detected in a given coverage are coming from the decay of the domains of DCC. This assumption might be valid when the detector coverage is same as the size of DCC domains. Let us consider a case when \( x \)-fraction of events analyzed has DCC like fluctuation carried by \( y \)-fraction of total pions. This is a realistic scenario when the size of the domain of DCC is smaller than the detector coverage. So for DCC pions we have \( \langle N \rangle_D = y \langle N \rangle \) and for generic pions we have \( \langle N \rangle_G = (1 - y) \langle N \rangle \), \( N \) being the total number of pions. The probability to find \( N_D \) pions carrying DCC signal will be given by \( P(N_D, N, y) = \binom{N}{N_D} y^{N_D} (1 - y)^{N - N_D} \), which would give \( \langle N(N - 1) \rangle_D = y^2 \langle N(N - 1) \rangle \). Now in this case the generating function of eq.11 will be replaced by

\[
G_{\text{obs}} = x' G_{\text{DCC}} + x G_{\text{DCC}} G_{\text{generic}} + (1-x-x')G_{\text{generic}} \tag{32}
\]
has all the photons are detected we have measured multiplicity (say in terms of experimentally observed quantities like mean and charge-to-neutral pion correlation to be related to mean multiplicities as
\[
\langle N_{\pi^\pm} \rangle = z \quad \text{and one finds mean-square of pion multiplicity and charge-to-neutral pion correlation to be related to mean multiplicities as}
\]

\[
\begin{align*}
\langle N_{\pi^0} \rangle &= \langle N_{\pi^\pm} \rangle + \langle N_{\pi^0} \rangle^2 \\
\langle N_{\pi^\pm} \rangle &= \langle N_{\pi^\pm} \rangle + \langle N_{\pi^0} \rangle^2 \\
\langle N_{\pi^0}N_{\pi^\pm} \rangle &= \langle N_{\pi^0} \rangle \langle N_{\pi^\pm} \rangle
\end{align*}
\]

(37)

where \( z \) is the single particle partition function. In ref[20] it was shown that for an ideal scenario where one assumes the total isospin of the system to be zero, above mentioned relationships will become complicated. An ensemble of the total isospin I=0 gives

\[
\langle N_{\pi^0} \rangle = \langle N_{\pi^\pm} \rangle = \frac{z^2}{3} + \frac{z^3}{6}
\]

(38)

but the mean-square pions multiplicities are modified as

\[
\begin{align*}
\langle N_{\pi^0} \rangle &\approx \langle N_{\pi^\pm} \rangle + \frac{z^2}{3} + \frac{z^4}{15} \\
\langle N_{\pi^\pm} \rangle &\approx \langle N_{\pi^\pm} \rangle + \frac{z^4}{10}.
\end{align*}
\]

(39)

We can generalize this result and apply in case of our observables of \( \gamma - \text{ch} \) correlation. The dependence on \( z \) can be eliminated and final observables can be expressed in terms of experimentally observed quantities like measured multiplicity (say \( \sqrt{\langle N_{\text{ch}} \rangle \langle N_{\gamma} \rangle} \)). In this case one has \( \langle N_{\gamma} \rangle = 2 \langle N_{\pi^0} \rangle \) and \( \langle N_{\text{ch}} \rangle = \langle N_{\pi^+} + N_{\pi^-} \rangle = 2 \langle N_{\pi^\pm} \rangle \). Also for decay of neutral pions, in case when all the photons are detected we have\(^2\) \( \sigma_{\gamma}^2 \approx 2\sigma_{\pi^0}^2 \). One can express the mean-square multiplicity to be

\[
\begin{align*}
\langle N_{\gamma}^2 \rangle &= 4 \langle N_{\pi^0}^2 \rangle, \\
\langle N_{\text{ch}}^2 \rangle &= 2 \langle N_{\pi^\pm}^2 \rangle + 2 \langle N_{\pi^+} + N_{\pi^-} \rangle
\end{align*}
\]

(40)

and the correlation term will be given by \( \langle N_{\gamma}N_{\text{ch}} \rangle = 4 \langle N_{\pi^0} \rangle \langle N_{\pi^\pm} \rangle \). Now we have

\[
\begin{align*}
\frac{f_{20}}{f_{10}^2} &= \frac{1}{2} \left( \frac{\langle N_{\pi^\pm}(N_{\pi^\pm} - 1) \rangle + \langle N_{\pi^+}N_{\pi^-} \rangle}{\langle N_{\pi^\pm} \rangle^2} \right) \\
\frac{f_{62}}{f_{20}^2} &= \frac{1}{2} \left( \frac{\langle N_{\pi^0}(N_{\pi^0} - 1) \rangle}{\langle N_{\pi^0} \rangle^2} + 1 \right) \\
\frac{f_{11}}{f_{10}f_{01}} &= \frac{\langle N_{\pi^0}N_{\pi^\pm} \rangle}{\langle N_{\pi^0} \rangle \langle N_{\pi^\pm} \rangle}
\end{align*}
\]

(41)

So using eq(37) eq(39) and eq(41) we can estimate \( \nu_{\gamma\text{ch}}^{\gamma\text{ch}} \) and \( r_{1,1} \) for GCE and I=0 systems. Using eq(13) we can estimate \( \Delta\nu_{\gamma\text{ch}}^{\gamma\text{ch}} \). For GCE we get from eq(37) and eq(41) \( \nu_{\gamma\text{ch}} = 1/\sqrt{\langle N_{\text{ch}} \rangle \langle N_{\gamma} \rangle} \), which gives correct multiplicity dependence as predicted from CLT. So we have \( \Delta\nu_{\gamma\text{ch}}^{\gamma\text{ch}} = 0 \) for GCE. The system of I=0 gives \( \Delta\nu_{\gamma\text{ch}}^{\gamma\text{ch}} \sim -0.98/\sqrt{\langle N_{\text{ch}} \rangle \langle N_{\gamma} \rangle} \) which also agrees with the CLT predictions as shown in fig 2(b). In case of GCE \( r_{1,1} \) is predicted to be \( 2/(1 + 1/\sqrt{\langle N_{\text{ch}} \rangle \langle N_{\gamma} \rangle}) \) which becomes 1 for large values of multiplicity. For system of I=0 \( r_{1,1} \sim 1 \) for all values of \( \sqrt{\langle N_{\text{ch}} \rangle \langle N_{\gamma} \rangle} \) as shown in fig 2(a).

We have estimated various observables and their centrality dependence using different monte-carlo event generators like HIJING[27], AMPT[28] and UrQMD[29] for top RHIC energy. For our calculation we choose one unit

---

2 For Poissonian case \( \sigma_{\gamma} = \sqrt{\langle N_{\gamma} \rangle} = \sqrt{2\langle N_{\pi^0} \rangle} = \sqrt{2\sigma_{\pi^0}} \).
At lower multiplicities they have qualitatively different nature probably due to presence of various other effects in the monte-carlo models.

Fig. 3(a) shows the variation of $r_{m,1}$ with its order $m$. Results from all the model are consistent with the generic case of pion production. Fig. 3(b) shows the centrality dependance of $\nu_{dyn}$ and $\Delta \nu_{dyn}$ predicted from HIJING. For comparison of centrality dependance predicted from CLT, we have fitted the points with functional form of $A + B/\sqrt{\langle N_{ch} \rangle \langle N_{\gamma} \rangle}$. This yields a value of $A \approx 5 \times 10^{-5}$ and $B = -0.6$ for $\Delta \nu_{dyn}$. We also note here that the sign of $\Delta \nu_{dyn}$ is negative for low multiplicity. This means that the Raw HIJING includes some intrinsic $\gamma$ - $ch$ correlation making the last term of eq. 11 to dominate over individual fluctuation. This can be attributed to the resonance decays present in HIJING model. For DCC like signal sign of $\Delta \nu_{dyn}$ should become positive for all centralities.

VIII. DCC MODEL

We have tried to implement DCC like anti-correlation signals in HIJING events. For a given event we changed the neutral pion fraction to follow $1/\sqrt{f}$ like distribution by flipping $\pi^0$ to $\pi^\pm$. And finally we decay the neutral pions to photons. In the process of flipping we make sure that the charge and isospin conservations are maintained. Fig. 4 shows the $f$-distribution after the implementation of DCC in HIJING. For generic event the neutral pion fraction is peaked at 1/3 and for DCC events it has a long tail. Since the variation of DCC like domain formation with rapidity and azimuthal angle is not known, we perform this flipping for all the particles. This produces $1/2\sqrt{f}$ like distribution over all phase space. To make the scenario more realistic we do the calculation of the final variables using total number of detected photons and charged particles rather than considering only pions.

\[ \frac{1}{2} \\sqrt{f} \]

---

*both STAR and ALICE experiments has the setup of simultaneous measurements of charged and photon in one unit of rapidity.*
Other dominant sources of photons and charged particles include $\eta$, charged kaons and protons respectively. It is difficult to extract the fraction of primordial pions on which the DCC-like probability distribution could be implemented. HIJING has minijet like environment in which the production mechanism are “string fragmentation” and the abundance of particles are weighted by the spin giving large fraction of pions coming from decay of resonances. The primordial pions coming directly from string fragmentation are much smaller. Alternative environment like hydro models where the massive resonances are exponentially suppressed would give large fraction of soft pions. The difference between the two models of string fragmentation and hydro is recently contested in ref. [30]. We therefore randomly choose pions produced in HIJING events, treat them to be thermal and implement $1/2\sqrt{f}$ distribution. Fig. 5 shows the central-

(b) Variation of $\nu_{\text{dyn}}$ with multiplicity

**FIG. 5:** Multiplicity dependence of observables $r_{1,1}$ and $\nu_{\text{dyn}}$ as predicted from DCC implemented HIJING model. Here $N_{\text{ch}}$ and $N_{\gamma}$ denotes the mean multiplicities of charged particles and photons for various centralities. The gray band shows the statistical error in model calculation.

![Variation of $r_{m,1}$ in DCC events with fraction of pions coming from decay of DCC domains](image3)

(a) Value of $r_{m,1}$ with $m$ for various fraction of DCC events. The solid markers are when $N_{\text{ch}}$ and $N_{\gamma}$ includes all the charged particles and photons and the hollow markers are when only pions are source of charged particles and photons. The curves are estimations from eq. 36 and points are from DCC implemented HIJING.

**FIG. 6:** Sensitivity of $r_{m,1}$ to DCC like signals, estimation shown for $x = 1$.
similar dependence for all higher moments of \(r_{m,1}\). Absolute values of \(r_{1,1}\) are consistent with the prediction \(r_{1,1} = (5 - 2x)/(5 + x)\) from eq.\(17\). For higher fraction of DCC the centrality dependence has slight non-monotonic behavior. This is also seen in \(\Delta \nu_{\text{dyn}}\). As expected from eq.\(16\), the values of \(\Delta \nu_{\text{dyn}}\) show proportionality with the fraction of DCC events. The absolute values of \(\Delta \nu_{\text{dyn}}\) are also very close to \(\approx x/(5/9)\) as predicted in eq.\(16\). The centrality dependence causes \(\approx 15\%\) variation of the values of most central to peripheral events for \(\Delta \nu_{\text{dyn}}\). Fig.\(6\)(a) shows that the variation of \(r_{m,1}\) with \(m\). The results from model match the theoretical curve (eq.\(17\)) when one considers only pions as source of charged particles and photons, however when all other sources are considered the results are off towards lower side. A more detailed study of the sensitivity to fraction of DCC pions is shown in Fig.\(6\)(b). We have shown the sensitivity of \(r_{m,1}\) with the fraction of detected pions carrying DCC-signals. In fig.\(6\)(b) we also plot the curves obtained from eq.\(36\). The effect of resonances present in HIJING seems to be resulting in reduced sensitivity of \(r_{m,1}\) for lower fraction of DCC pions.

IX. SUMMARY

We have developed a procedure for generalization of methods for studying \(\gamma\)-charge correlation in heavy-ion collisions. One of the primary motivations for this study could be the search for DCC-like anti-correlation signals relevant to the ongoing heavy ion program at RHIC and LHC. We have discussed the robustness of two variables \(\Delta \nu_{\text{dyn}}\) and \(r_{m,1}\) and have studied their centrality(multiplicity) dependence. The sensitivity of the variables have been studied with the fraction of DCC type events(\(x\)) and the event wise fraction of DCC pions(\(y\)). These variables where evaluated from different models which do not include the physics of DCC. We have also developed a Monte-Carlo model where DCC domains have been implemented in HIJING to see the sensitivity of those variables with DCC signals. Our results show that the model predictions of the variables are consistent with the theoretical predictions using generating function approach.

We have implemented the detector effects like efficiency of detection, mis-identification into study the effect on observables. The mis-identification factor reduces the effective signal strength for which an approximate expression has been derived in generating function approach. \(r_{m,1}\) has been found to be more robust towards mis-identification of photons as compared to \(\Delta \nu_{\text{dyn}}\). The resonance decay can induce correlation which can suppress the anti-correlating DCC signal. A quantitative idea of resonance can be obtained from Monte Carlo model that implements DCC in which we can vary the number of DCC candidates and see the sensitivity of \(r_{m,1}\).

We have seen that the variable \(\Delta \nu_{\text{dyn}}\) is highly sensitive to the fractions \(x\) and \(y\). In a given centrality \(\Delta \nu_{\text{dyn}}\) is proportional to \(xy^2\). For generic case of particle production from CLT, it is predicted to be inversely proportional to multiplicity. The sign of \(\Delta \nu_{\text{dyn}}\) would indicate the dominance of correlation over anti-correlation.

We also discuss the applicability of the Minimax variable \(r_{m,1}\) for heavy-ion collisions. \(r_{m,1}\) seem to be flat with centrality. Higher orders of \(r_{m,1}\) shows larger sensitivity \(x\) and can have contribution up to \(y^{m+1}\). A simplified form of the functional dependence of \(r_{m,1}\) with \(m\) has been calculated in generating function approach for lowest order of \(y^2\). This would be useful to restrict the signal strength \(xy^2\) by fitting the experimental data.

X. APPENDIX

A. Mixed events

While analyzing data sample to calculate \(\nu_{\text{dyn}}^{\gamma -\text{ch}}\), one can estimate the generic term by doing a mixed event analysis. A simple method we prescribe is to take total number of photons and total number of charge particles from different events would only effect correlation terms like \(f_{11}\) in \(\nu_{\text{dyn}}^{\gamma -\text{ch}}\) keeping other factorial moments unchanged. In such case we must have

\[
\frac{f_{11}}{f_{10} f_{01}} \approx \frac{\langle N(N - 1) \rangle}{\langle N \rangle^2}.
\]

Taking a particular combination of factorial moments we can calculate the generic value for \(\nu_{\text{dyn}}\) we need to calculate \(\Delta \nu_{\text{dyn}}\). For example one can show that

\[
\left( 3 \frac{f_{11}}{f_{10} f_{01}} - 4 \frac{f_{20}}{f_{10}^2} + \frac{f_{02}}{f_{01}^2} \right) \left|_{\text{mixed}} \right. = \frac{1}{2 \langle f \rangle \langle N \rangle}.
\]

which is equal to \(\nu_{\text{dyn}}^{\text{generic}}\). But in case of contamination effects present in the data sample one cannot apply this simple method since in that case the efficiency terms cannot be eliminated from \(\nu_{\text{dyn}}\). A full GEANT simulation with a known event generator which doesn’t include the physics of DCC is suggested to estimate the generic value of \(\nu_{\text{dyn}}\).

B. Mis-identification

In case of mis-identification of photon as charge particles and vice-versa the factorial moments are modified
as given in eq[20] The observables $\Delta \nu_{\text{dyn}}$ and $r_{m,1}$ will be given by

$$
\Delta \nu_{\text{dyn}} = \frac{\left( \langle (1 - f) \varepsilon_{ch} + 2 f \varepsilon_{\gamma, ch} \rangle^2 \right) - \langle (1 - f) \varepsilon_{ch, \gamma} + 2 f \varepsilon_{\gamma} \rangle^2}{\langle (1 - f) \varepsilon_{ch} + 2 f \varepsilon_{\gamma, ch} \rangle^2 - \langle (1 - f) \varepsilon_{ch, \gamma} + 2 f \varepsilon_{\gamma} \rangle^2} \frac{\langle (N(N - 1) (1 - f) \varepsilon_{ch} + 2 f \varepsilon_{\gamma, ch}) \rangle}{\langle (N(N - 1) (1 - f) \varepsilon_{ch} + 2 f \varepsilon_{\gamma, ch}) \rangle^2} (N(N - 1)) \langle (1 - f) \varepsilon_{ch, \gamma} + 2 f \varepsilon_{\gamma} \rangle \langle (1 - f) \varepsilon_{ch, \gamma} + 2 f \varepsilon_{\gamma} \rangle^2
$$

$$
r_{m,1} = \frac{\langle (N(N - 1) (1 - f) \varepsilon_{ch} + 2 f \varepsilon_{\gamma, ch}) \rangle}{\langle (N(N - 1) (1 - f) \varepsilon_{ch} + 2 f \varepsilon_{\gamma, ch}) \rangle^2} \langle (1 - f) \varepsilon_{ch} + 2 f \varepsilon_{\gamma, ch} \rangle^m + 2 N f \langle (1 - f) \varepsilon_{ch} + 2 f \varepsilon_{\gamma, ch} \rangle \langle (1 - f) \varepsilon_{ch, \gamma} + 2 f \varepsilon_{\gamma} \rangle \langle (1 - f) \varepsilon_{ch, \gamma} + 2 f \varepsilon_{\gamma} \rangle^2
$$

In case of $\varepsilon_{\gamma, ch} = \varepsilon_{\gamma, 2ch} = 0$ one recovers eq[21] and eq[24] which are given by

$$
f_{11} = \frac{2 y (1 - y) \langle f \rangle (1 - f) \langle N \rangle^2 + \langle (1 - xy(2 - y)) \rangle f(1 - f) \langle N(N - 1) \rangle}{2 \varepsilon_{\gamma} \varepsilon_{\gamma}}
$$

$$
f_{20} = \frac{2 y (1 - y) \langle (1 - f)^2 \langle N \rangle^2 + \langle (1 - xy(2 - y)) \rangle f(1 - f) \langle N(N - 1) \rangle}{2 \varepsilon_{\gamma} \varepsilon_{\gamma}}
$$

$$
f_{02} = \frac{2 y (1 - y) \langle f^2 \rangle \langle N \rangle^2 + \langle (1 - xy(2 - y)) \rangle f(1 - f) \langle N(N - 1) \rangle}{2 \varepsilon_{\gamma} \varepsilon_{\gamma}}
$$

which gives

$$
r_{1,1} = \frac{5 - 2 x y^2}{5 + x y^2}
$$

$$
r_{2,1} = \frac{35 - x y^2 (21 - 4 y)}{35 + x y^2 (21 - 2 y)}
$$

and so on. The general formula for $r_{m,1}$ is given by

$$
r_{m,1} = 1 - \frac{m x y^2}{(m + 1)} F(m, x y^2) + O(x y^3) \cdots
$$

which is same as the case corresponding to $y = 1$. But higher order moments are modified to be

$$
r_{m,1} \approx 1 - \frac{m x y^2}{(m + 1)} F(m, x y^2)
$$
