Full self-consistent stationary Vlasov-Maxwell solutions of magnetically confined plasmas are built for systems with cylindrical symmetries. The stationary solutions are thermodynamic equilibrium solutions. These are obtained by computing the equilibrium distribution function resulting from maximizing the entropy and closing the equations with source terms that are then computed by using the obtained distribution. This leads to a self-consistent problem corresponding to solving a set of two coupled second order non-linear differential equations. Relevant plasma parameters are introduced and a bifurcation leading to an improvement of plasma confinement is shown. Conversely in the improved confinement setting, we exhibit the emergence of a separatrix in the integrable motion of a charged particles.

I. INTRODUCTION

Within the scope of the search for better containment of Tokamak-based fusion plasma, understanding the emergence of transport barriers is a major issue. Indeed, they may give rise to the so-called H-mode which is in the heart of the current approach of magnetically confined fusion reactor. And it now seems accepted that the internal transport barrier (ITB) play a major role in magnetized fusion plasma [1, 2].

When considering magnetized fusion plasma, it is now commonly accepted that one of the best description of the plasma is the kinetic one coupled to the Maxwell equations, and due to the low collisionality of the plasma the Maxwell-Vlasov system becomes de facto the first choice. The Vlasov equation is a common feature observed when considering systems with long range interactions, and beyond plasmas a large number of physical systems are in this category, like for instance gravitational forces and Coulomb interactions, vortices in two dimensional fluid mechanics [3–6], wave-particle systems relevant to plasma physics [7–9], Free-Electron Lasers (FELs) [10, 11]. In these settings, long range interacting Hamiltonian systems display some common dynamical features. Given some initial condition the systems exhibit a rapid relaxation towards a quasi-stationary state (QSS). These QSS have extended lifetime, and one way to tackle them in statistical mechanics is to use the Lynden-Bell formalism [12, 13]. In the realm of long range models the Hamiltonian mean field (HMF) model [14] has emerged as being a paradigmatic one, displaying most of the features observed in systems with long range interactions: non-additivity [15], out of equilibrium phase transition [16, 17], long lived quasi-stationary states and slow relaxation towards equilibrium. More recently the Hamiltonian microscopics dynamics has been investigated and displayed surprising regularity [18], and lead to the understanding of stationary states of the problem as a self-consistent infinite collection of uncoupled thus integrable pendula [19] and this could be extended to other models [20]. This regularity lead to the idea that long range systems organized themselves in terms of self-organized regularity [21], at least when it was possible, i.e the underlying microscopic dynamics became integrable once an equilibrium was reached and the self-consistent fields were thus stationary, this was also the case for the true thermodynamic equilibrium. Given this feature, we will take a similar approach in the context of plasma physics and following the recent results discussed in [22, 23]. We construct complete thermodynamic equilibrium solutions of the classical Maxwell-Vlasov equations in a cylindrical geometry in the spirit of already discussed equilibria [24–28]. Indeed in this geometry the motion of a charged particle in a two-component magnetic field can be made integrable, while it is not guaranteed in a toroidal configuration [29]. After applying the recipes we find stationary solutions of the Maxwell-Vlasov problem in this geometry, are obtained after solving a system of two coupled nonlinear ordinary differential equations. In this paper, these equations are computed and then solved and regimes leading to a plasma confinement are discussed and investigated, the influence of plasma flows is thoroughly investigated and a bifurcation leading to an improved plasma confinement is presented; this is reminiscent at least formally to what one expect from the H-mode. Another important question that arises is whether or not the integrable individual microscopic dynamics resulting from the obtained self-consistent field can have a separatrix in their phase space. Indeed when only taking into account the self-consistency partially [22], it was shown that no separatrix could exist, while as will be shown taking into account the full self-consistency can lead to the emergence of a separatrix. This feature is quite crucial, as it was shown in [29, 30] that when moving to a toroidal configuration the breaking of the separatrix was leading to Hamiltonian chaos and accompanying this large fluctuation of the magnetic moment are observed and it can not be considered an adiabatic invariant [31, 32], this should affect the foundations of gyrokinetics [33], and as such the results obtained through
gyrokinetic simulations could not be considered as “first principles”.

Finally one last benefit of having exact solutions of the Valslov-Maxwell system is that besides their physical relevance which can shed some different point of views on fusion plasma, if proved to be stable, the solutions could be used as well as tests for numerical codes like for instance the one discussed in \cite{34} as part of their validation process.

The paper is organized as follows, in a first part we briefly recall the recipes of the problem that were used in \cite{22,23} and extend it by taking into account the poloidal current feedback. We introduce as well the relevant physical plasma parameters that are at the core of our analysis. Then in section II, we quickly derive the equations that allows to study the different possible regimes, the full derivation and computations of a two species plasma being derived in the appendix. The solutions are studied in section III, and a bifurcation between two regimes is exhibited and the individual microscopic dynamics is discussed. Finally we conclude.

II. FULL SELF-CONSISTENT EQUILIBRIUM EQUATIONS

In this section we present the two nonlinear coupled ordinary differential equations that govern the self-consistent equilibrium solutions of the Maxwell-Vlasov problem in the considered cylindrical geometry. In order to do so, let us start by describing our considered setting.

A. Electromagnetic setting

We consider the problem of an infinite aspect ratio limit of an ideal Tokamak such that we can consider the torus as a cylinder and the usual cylindrical coordinates \((r, \theta, z)\) and associated unit vectors \((e_r, e_\theta, e_z)\). In this setting, we consider a magnetic field with cylindrical symmetry \(B(r)\) in the following form

\[
B = B_{\text{Plasma}} + B_{\text{Ext}}
\]

where \(B_{\text{Ext}} = B_0 e_z\) is an external uniform magnetic field of intensity \(B_0\) applied to the plasma, and \(B_{\text{Plasma}}\) is the magnetic field generated by the plasma. In order to comply with the symmetry we choose to consider magnetic fields that can be expressed as

\[
B = B_0 \left[ g(r) e_\theta + (1 + k(r)) e_z \right]
\]

where \(g\) and \(k\) are two functions that remain to be determined, and correspond to the plasma generated field, i.e. \(B_{\text{Plasma}} = B_0 \left[ g(r) e_\theta + k(r) e_z \right]\). From this we can get an expression of the vector potential

\[
A = A_\theta(r) e_\theta + A_z(r) e_z
\]

in a Coulomb gauge which introduces two other related functions \(K(r)\) and \(G(r)\):

\[
A_\theta(r) = \frac{B_0}{r} \int_0^r u (1 + k(u)) \, du = \frac{B_0}{r} \left( \frac{r^2}{2} + K(r) \right)
\]

and

\[
A_z(r) = -B_0 \int_0^r g(u) \, du = -B_0 G(r).
\]

So, the magnetic potential \(A(r)\) writes

\[
A(r) = B_0 \left[ \left( \frac{r^2}{2} + \frac{K(r)}{r} \right) e_\theta - G(r) e_z \right].
\]

Finally, we will assume that there is no electric field, by for instance considering there is some neutralizing background or that the charge density is zero using a two species approach (this is detailed in the appendix A).

B. Charged particle dynamics

We will consider the motion of a charged particle in the fields described previously. We shall assume that we have a classical non-relativistic point particle with charge \(Q = 1\) and mass \(m = 1\). Using the canonical variables, the motion is Hamiltonian and the Hamiltonian of the system writes

\[
H = \frac{(p - A(q))^2}{2},
\]

where \(p\) and \(q\) form three pairs of canonically conjugate variables.

The associated equations of motions are :

\[
\begin{align*}
\dot{q} &= p - A \\
p &= \nabla A \cdot (p - A).
\end{align*}
\]

Given the specific form of the magnetic field and the associated symmetries (translation along \(z\), and rotation around \(\theta\)), the motion of charged particles is integrable and we can reduce the system to an effective one-dimensional Hamiltonian system

\[
H = \frac{1}{2} \left[ p_\theta^2 + \left( p_\theta - B_0 \left( \frac{r}{2} + \frac{K(r)}{r} \right) \right)^2 + (p_z + B_0 G(r))^2 \right]
\]

\[
= \frac{p_\theta^2}{2} + V_{eff}(r),
\]

where \(p_\theta\) and \(p_z\) are constants of the motion see for instance \cite{22}.
C. Kinetic approach and equilibrium stationary distribution

In order to describe the plasma, we take a kinetic point of view and will consider a one particle distribution function at equilibrium in order to describe the physical state of the plasma. As mentioned we consider no electric field and neglect the collisions, so we can assume that the dynamics of the distribution function is governed by the Vlasov equation, and in our non-relativistic setting it corresponds to the conservation of the particle distribution function along the trajectory of each particle, i.e.:

$$\frac{d}{dt} f(q, p, t) = 0 \quad (11)$$

where \(q\) and \(p\) satisfy (8). More information can be found in [35, 36] for example. The particles are sources for the fields in the Maxwell equations, and we have the source terms \(n\) for the spatial density function of charges, and \(j\) for the current vector, are given by

$$n(q,t) = \int_{-\infty}^{+\infty} f(q, p, t) \, d^3 p \quad (12)$$

and

$$j(q, t) = \int_{-\infty}^{+\infty} v f(q, p, t) \, d^3 p \quad (13)$$

Since the motion of particles is governed by the magnetic field, this implies a self-consistent problem [37]. In what follows we derive a possible candidate of the stationary distribution function by following the steps of the procedure described in [22, 23]. Note that the full derivation of the equations is done in the appendix, and for clarity we decided to go as straight as possible to the self-consistent equations to be solved.

When looking for a stationary solution of the non self-consistent Vlasov equation (11), we can rewrite it with the usual Poisson bracket as

$$\{f, H\} = 0 \quad (14)$$

and so any function of \(H\) is a solution of the problem.

Furthermore, when building the distribution function coming from integrable microscopic motion we want to consider the fact that the total energy of the system \(H\), the total momentum along \(z\), and the total angular momentum along \(\theta\) are conserved. Accordingly, the Poisson bracket with one of these conserved quantities is null. So, we can introduce respectively four Lagrange multipliers \(\beta, \gamma_z, \gamma_\theta\) and \(\gamma_\phi\) in order to impose constraints corresponding to these conserved quantities, respectively the energy, the momentum along \(z\), the angular momentum and the number of particles conservation. And, in order to select a solution among the infinite possibilities, we settled for the one which maximize the entropy

$$S[f] = -k_B \int f \ln(f) \, d\Omega \quad (15)$$

where \(k_B\) is the Boltzmann constant and \(d\Omega\) the infinitesimal volume of the phase space \(\Gamma\), with the previously mentioned constraints. In order to fully characterize our problems, since we considered solutions with translation invariance, the relevant quantity is the lineic particle density instead of the total number of particles which should become infinite in this setting. Another way to circumvent this is to consider that we have some kind of periodicity in the cylinder (some kind of flat torus), so that the total \(N\) particles are confined within a length \(2\pi R\) of the cylinder, corresponding to a lineic particle density \(\lambda = N/2\pi R\). The solutions to this variational problem are given by a distribution of the form

$$f \propto e^{-\beta H - \gamma_z p_z - \gamma_\theta p_\theta} \quad (16)$$

We can get the exact expression knowing the total number of particles \(N\), indeed we choose to normalize \(f\) such that

$$N = \int_{\Gamma} f \, d\Omega \quad (17)$$

and so the proportionality constant is

$$f_0 = \frac{N}{4\pi^2 R \left(\frac{2\pi}{\gamma_1}\right)^{3/2} \int_0^{+\infty} re^{-ar^2 - bG(r) - cK(r) - \gamma_1} \, dr} \quad (18)$$

with \(\gamma_1 = -\frac{2^2}{\beta^3} a = \frac{\gamma_\theta}{2} \left(B_0 - \frac{\gamma_\theta}{2}\right), b = -B_0 \gamma_z, c = B_0 \gamma_\theta\). That leads to the final expression

$$f = \frac{Ne^{-\beta H - \gamma_z p_z - \gamma_\theta p_\theta}}{4\pi^2 R \left(\frac{2\pi}{\gamma_1}\right)^{3/2} \int_0^{+\infty} re^{-ar^2 - bG(r) - cK(r) - \gamma_1} \, dr} \quad (19)$$

It may be worth noting here that the \(\beta\) parameter corresponds to the thermodynamic temperature

$$\frac{1}{k_B T} = \frac{\delta S}{\delta E} = \beta \quad (20)$$

and it can be assumed positive. We also insist on the fact that \(\gamma_\theta\) and \(\gamma_z\) are proportional to the averages of \(v_\theta = r\dot{\theta}\) and \(v_z = \dot{z}\) respectively. In the literature [23], it has been noted that when a plasma rotation exists an ITB can exist. Then, it can be expected that in such states the averages of \(v_\theta\) and \(v_z\) are not null and so are \(\gamma_\theta\) and \(\gamma_z\) respectively.
D. Sources of the plasma magnetic field

Always considering only one species of a charged particle with charge $Q = 1$ and mass $m = 1$, we can compute the particle density, and the current density in the plasma from the form of the resulting distribution function (19) and the Hamiltonian (9), and extract an explicit form of the source terms which depends on the functions $G$ and $K$. For instance, the radial density $n$ behaves like

$$n(q) \propto e^{-ar^2 - bG(r) - cK(r)}.$$  

We also compute the proportionality term and express the radial density $\rho$ given by

$$\rho(r) = \frac{\int n(q) r \, d\theta \, dz}{\int r \, d\theta \, dz} = \frac{1}{4\pi R} \int n(q) \, r \, d\theta \, dz$$

as

$$\rho(r) = \frac{1}{\gamma} e^{-ar^2 - bG(r) - cK(r)}.$$  

We notice that as discussed in [23], the equation (23) shows that the equilibrium profile is not flat as soon as $\gamma_\theta$ is not zero and it depends on the poloidal magnetic field configuration when $\gamma_z \neq 0$. In other words as soon as the plasma moves the profiles are not flat. Moreover, since we consider an equilibrium configuration, we obtain as well a non-flat temperature profile but we have to consider the local radial kinetic temperature profile, rather than the thermodynamic one (20) discussed previously. For instance we can compute the average kinetic energy at a constant radius

$$\varepsilon(q) = \int H f \, d^3p,$$  

that leads to

$$\varepsilon(q) = \frac{\partial n(q)}{\partial \beta}$$

which implies that the radial kinetic energy profile is proportional to the radial density and therefore has the same shape.

In the same spirit we now compute the source terms of the plasma magnetic field and move to the current density $j$. We start directly from (13) and the speeds

$$v_z = p_z + B_0 G(r)$$

and

$$v_\theta = \frac{p_\theta}{r} - B_0 \left( \frac{r}{2} + \frac{1}{r} K(r) \right).$$  

So, if we break down $j$ by component, the density current along the $\theta$-coordinate is given by

$$j_\theta(q) = \int_{-\infty}^{+\infty} v_\theta f \, dp_r \, dp_z \, dp_\theta$$

and ends up as

$$j_\theta(q) = -\frac{1}{\gamma} \frac{\gamma_\theta}{\beta} e^{-ar^2 - bG(r) - cK(r)}.$$  

For the density current along the $z$-coordinate, we do the same

$$j_z(q) = \int_{-\infty}^{+\infty} v_z f \, dp_r \, dp_z$$

and we obtain

$$j_z(q) = -\frac{1}{\gamma} \frac{\gamma_z}{\beta} e^{-ar^2 - bG(r) - cK(r)}.$$  

So we finally find

$$j(r) = -\frac{1}{\gamma} \left( \frac{\gamma_\theta}{\beta} r \, e_\theta + \frac{\gamma_z}{\beta} e_z \right) e^{ar^2 - bG(r) - cK(r)},$$

or when rewritten as a function of radial density

$$j(r) = \left( \frac{\gamma_\theta}{\beta} r \, e_\theta + \frac{\gamma_z}{\beta} e_z \right) \rho(r).$$

Now that the source terms have been computed we may move to the self-consistent solutions. However we can already notice that the solutions will obey an interesting condition that is independent of the thermodynamic temperature:

$$\frac{j_\theta(r)}{r j_z(r)} = \frac{\gamma_\theta}{\gamma_z}.$$  

E. General Self-Consistent Equation

We have computed the currents which depend on the functions $K$ and $G$ that are defining the vector potential (6) in Coulomb gauge ($\nabla \cdot A = 0$) which itself is related to the current through Ampère’s law and ends up to be a Poisson equation

$$\Delta A = -\mu_0 j.$$  

and so, using the previously computed source terms we obtain a set of self-consistent equation

\[
\begin{align*}
\frac{1}{r} \frac{\partial}{\partial r} \left( r \frac{\partial K(r)}{\partial r} \right) - \frac{\partial}{\partial r} \left( r \frac{\partial G(r)}{\partial r} \right) &= \kappa_\theta e^{-ar^2 - bG(r) - cK(r)} \\
\frac{1}{r} \frac{\partial}{\partial r} \left( r \frac{\partial G(r)}{\partial r} \right) &= \kappa_z e^{-ar^2 - bG(r) - cK(r)}
\end{align*}
\]  

(37)

with

\[
\kappa_{\theta \rightarrow z} = \frac{\mu_0}{B_0 \beta} \gamma \theta \gamma \theta z.
\]  

(38)

A full derivation of these equations when considering a two species neutral plasma is performed in Appendix A, and we end up with the same form as expressions (37).

Let us now study more the system (37). First in order to simplify and given the relation (35), we rescale the length using a scaling of the type \( \tilde{r} \rightarrow \frac{\gamma \theta}{\gamma \theta z} r \). Furthermore, if we also do the transformations \( \tilde{G}(r) \rightarrow bG(r) \) and \( \tilde{K}(r) \rightarrow ar^2 + cK(r) \), and finally we set \( \tilde{j}_z(\tilde{r}) = \alpha e^{-G(\tilde{r}) - K(\tilde{r})} \) where \( \alpha = \frac{\langle j_z \rangle^2}{\sigma N} \) for the current density, we end up with

\[
\begin{align*}
\frac{1}{r} \frac{\partial}{\partial r} \left( r \frac{\partial \tilde{K}(\tilde{r})}{\partial r} \right) - \frac{\partial}{\partial r} \left( r \frac{\partial \tilde{G}(\tilde{r})}{\partial r} \right) &= \tilde{j}_z(\tilde{r}) \\
\frac{1}{r} \frac{\partial}{\partial r} \left( r \frac{\partial \tilde{G}(\tilde{r})}{\partial r} \right) &= \tilde{j}_z(\tilde{r}).
\end{align*}
\]  

(39)

For convenience we now omit the \( \gamma \), and forget the \( z \) in \( j_z \), also since we only have functions depending on \( r \), partial derivatives are simple ones. Working with Eq. (39) we have

\[
\frac{1}{r} \frac{d}{dr} \left( \frac{dK(r)}{dr} \right) = \frac{d}{dr} \left( G(r) \right)
\]  

and obtain

\[
\frac{dK(r)}{dr} = r^2 \frac{dG(r)}{dr} + \alpha_0 r
\]  

(41)

with the integration constant \( \alpha_0 \) that will need to be determined. Then from the logarithmic derivative of \( j(r) \) we obtain

\[
\frac{1}{j(r)} \frac{dj(r)}{dr} = -\frac{dG(r)}{dr} - \frac{dK(r)}{dr}.
\]  

(42)

And by combining these equations and differentiating (42) we end up with

\[
\frac{d^2j}{dr^2} = \left( \frac{2\alpha_0}{1 + r^2} + (1 + r^2)j \right) j + \left( \frac{1}{j} \frac{dj}{dr} - \frac{1 - r^2}{r(1 + r^2)} \right) \frac{dj}{dr}.
\]  

(43)

So we end up with one second order nonlinear ordinary differential equation, which once solved gives us the whole properties of the self-consistent Vlasov-Maxwell stationary state. Before solving it let us first discuss the conditions that need to be met for typical physical expected conditions, we insist that in contrast to the analytical work performed [22], here the full self-consistent field is taken into account and possible moderation effects on the external magnetic field are taken into account, leading to a set of differential equations (37) instead of just one.

\[\text{1. Constraints and parameters}\]

Let’s take a closer look at the parameters necessary for the integration of (43) in order to construct our Vlasov-Maxwell stationary solutions. Given the symmetry of the problem, it is natural to expect that \( \frac{dG(r)}{dr}(0) = 0 \), so only two parameters \( \alpha_0 \) and \( j(0) \) are needed to obtain the solution of (39). Then after fixing the plasma constants we will have access to the full Vlasov-Maxwell solution. The problem lies in connecting these two parameters with the global equilibrium parameters of the plasma which are \( \beta, \gamma \alpha, \gamma \theta \), and as well connect these to the external parameters, \( B_0 \) and the lineic average plasma density \( \lambda = N/2\pi R \). Note that we will assume that the unit length, i.e. the typical scale on which particles are confined, or a typical radius of the cylinder to be equal to 1, so \( 1/R \) has no dimension and can be more considered like for instance an aspect ratio if we imagine the cylinder as the limit of a torus. We shall now attempt to compute the two parameters from the global parameters, and start our analysis with \( \alpha_0 \).

For this purpose let us recall Eq. (41) and compute the constant in \( r = 0 \). Tracing back we obtain

\[
\alpha_0 = \left( \frac{\gamma \theta}{\gamma \theta z} \right)^2 \left[ 2a + c \left( \frac{1}{r} \frac{\partial G(r)}{\partial r} \right) \bigg|_{r=0} - b \left( \frac{r}{r} \frac{\partial G(r)}{\partial r} \right) \bigg|_{r=0} \right]
\]  

(44)

On the one hand, \( \left( \frac{r}{r} \frac{\partial G(r)}{\partial r} \right) \bigg|_{r=0} = 0 \) (from (5) we note that \( \frac{\partial G(r)}{\partial r} = g(r) \) and \( g(r) \) is bounded). On the other hand, from (4) we note that \( \left. \left( \frac{1}{r} \frac{\partial G(r)}{\partial r} \right) \right|_{r=0} = k(0) \). Given our cylindrical geometry, along \( z \) and for \( r = 0 \), the magnetic field \( B_z(0) \) corresponds to a solenoidal magnetic field which is the sum of the external \( B_0z \)-field and the field due to the current \( \frac{j_\theta}{2\pi R} = \int_0^{+\infty} j_\theta(r)dr \). So we end up with

\[
k(0) = \frac{\mu_0}{B_0} \int_0^{+\infty} j_\theta(r)dr = -\frac{\mu_0}{B_0} \frac{N}{4\pi^2 R \beta} \gamma \theta.
\]  

(45)

And thus

\[
\alpha_0 = \frac{\gamma \theta^2}{\gamma \theta} \left( B_0 - \frac{\gamma \theta}{\beta} \right) - \mu_0 \frac{\gamma \theta^2 N}{4\pi^2 R \beta}.
\]  

(46)

Regarding \( j(0) \), since the vector potential is defined up
Figure 1. Typical density profile here obtained with $j(0) = \alpha_0 = 1$.

to some constants, we end up with

$$j(0) = \alpha = \frac{(\kappa z)^2}{\kappa_0} \frac{\mu_0}{\kappa_0^2 \beta \mathcal{V}}$$  \hspace{1cm} (47)

unfortunately $\mathcal{V}$ depends on the integral of the function $j(r)/j(0)$, $j(r)$ depends on $j(0)$ and the differential equation (43) is nonlinear, so we have some implicit problem. Fortunately we have as well some constant parameters in $\mathcal{V}$, that we may adjust. So the strategy in what follows will be to fix a value of $\alpha_0$ and a value of $j(0)$, so we can obtain the function $j(r)$, from which the equilibrium will be defined.

III. SOLUTIONS

A. Standard equilibrium profiles

From the form of the solutions (43) and having the constants (46) and (47) more or less defined from plasma parameters, we can now compute and sketch some density current profile. Note that as well we consequently have access to the density profile since $\rho(r) \propto n(q) \propto j(r)$. In order to plot these profiles, we have to choose values for the parameters set $(j(0), \alpha_0)$. The solutions from the differential equation (43) are computed using octave (Isode) [38]. As we expected from [22], we get as well non flat “Gaussian” type profiles for a given choice of parameters (see figure 1). The quantity $j(0)$, as we can expect, is linked to the height of the $j(r)$ curve, conversely $\alpha_0$ appears to influence the shape of the profile.

B. Bifurcation towards enhanced confinement profiles

Regarding the behavior of the profile, for a fixed value of $j(0)$ a bifurcation with the emergence of a positive curvature and an enhanced density profile near $r = 0$ can be identified. To do so, we making some Taylor expansion near $r = 0$ and use the self-consistent equation (43). We find that the threshold $\frac{\partial^2 j}{\partial r^2} \bigg|_{t=0} = 0$ is obtained when

$$\frac{j(0)}{-2\alpha_0} = 1.$$  \hspace{1cm} (48)

from which we obtain solutions where the profiles exhibit a maximum in $r = 0$ and others with “eccentric” profiles, i.e a maximum of the density function for a given $r_0 > 0$. In order to study the different shape of solutions we choose to fix $j(0) = 1$ and we tune the parameter $\alpha_0$, results are displayed in figure 2.

We can notice also the role of the poloidal current density $j_\theta(r)$ depicted in figure 3, tends to be stronger and more peaked, i.e localized, once the bifurcation is crossed.

C. Link to hyperbolic points

Some evidence that steeper density profiles could be linked to the presence of hyperbolic points in particle trajectories have been made in [23]. In order to check if this is still the case with a self-consistent solution let us consider the effective potential defined in Eq. (10) and rewrite it with the scaled variables, we obtain
the functions related contribution negligible. We recall that here
the shape of the potential for different values of $\alpha$, we see that the current profile gets more peaked when $\alpha < -\frac{1}{2}$.

$$2\gamma^2 V_{\text{eff}}(r) = \left( \frac{2\gamma}{r} - \left( \frac{2\pi \lambda}{\rho_0} \frac{K(r)}{r} \right)^2 + (p_z - G(r))^2 \right).$$

(49)

To look for hyperbolic points, we need to check the shape of this potential, which obviously does not depend directly on $\gamma_z$, but we have to choose a value for the lineic density or the ratio $\lambda$ to determine an effective potential. In order to be somewhat realistic, we settled for an ITER like value of the parameter and fixed $\lambda \sim 10^{-20}$, making the related contribution negligible. We recall that here the functions $G$ and $K$ are actually $\tilde{G}$ and $\tilde{K}$ and are solutions from the self-consistent equations, and this influenced by the plasma parameters. Exploring now the shape of the potential for different values of $p_0$ and $p_z$, we find that there are effective potentials that give rise to unstable hyperbolic fixed point (see figure 4), we find these potentials once we have crossed the bifurcation threshold.

It is important also to point out the influence of diamagnetic effects due to the poloidal current, indeed when neglecting these effects it was not possible to obtain effective potentials with hyperbolic points (see [22]). In fact in figure 4, we can see the individual contribution of both terms in the effective potential, namely the one involving $G$ and the one involving $K$, and one clearly sees that both are needed to create the hyperbolic points in between the two two stable elliptic points. Moreover the presence of such effective potentials above the bifurcation threshold that creates an enhanced density profile is also consistent with the results depicted in [23]. This phenomenon could be indeed important as any perturbation will break the separatrix and lead to Hamiltonian chaos, like for instance considering these type of magnetic fields configuration in the torus with large aspect ratios, leads to chaos and destroys as well the magnetic moment and as such could impact the reliability of gyrokinetic simulations.

D. Back to plasma parameters

Now that we have briefly analyzed the solutions that we get, we want to summarize what are the plasma parameters corresponding to these solutions and discuss them. We list them in three categories

**External constraints:** $R, B_0$

**Microscopic physics:** $m^-, m^+, q^-, q^+$

**Plasma parameters:** $N, \beta, \gamma_0, \gamma_z$

We shall below consider only the one species solution discussed previously. We recall that the characteristic length scale of the systems is given by

$$r = \frac{\gamma_z}{\gamma_0}. \quad (50)$$

We then have $\alpha_0$ given by Eq. (46) and $j(0)$ by Eq. (47).

We can then for instance compute the poloidal and toroidal current by computing the flux of $J$, that leads to the currents

$$I_\theta = -qN \frac{\gamma_0}{2\pi \beta}, \quad (51)$$

$$I_z = -qN \frac{\gamma_z}{2\pi R \beta}. \quad (52)$$
Or the typical speed of the plasma along both directions

\[
\frac{\langle v \rangle}{N} = - \left( \frac{2 \gamma_z \langle v \rangle}{\beta^2} \right).
\]

(53)

We may as well compute the energy density

\[
\frac{\langle H \rangle}{N} = \left[ \frac{3}{2 \beta} + \frac{m \gamma_z^2 \langle v^2 \rangle}{2 \beta^2} \right] + \frac{m \gamma_z^2}{2 \beta^2}.
\]

(54)

that corresponds to the average kinetic energy of the particles, we see here that due to the plasma flow we do not have the usual direct link between \( \beta \) and the kinetic energy per particle and additional terms appear.

In order to see if these stationary solutions could be relevant in the context of magnetized fusion, we as well compute some order of magnitudes, considering \( T \sim 10 \text{keV}, \ B_0 \sim 1 \text{T}, \ N \sim 10^{20} \text{m}^{-3}, \ m \sim 10^{-27} \text{kg} \) and \( Q = e \). Let us consider a distribution with \( a \sim 10, \ b \sim 10 \) and \( c \sim 10 \), like what was done in [23]; we also want our typical scale \( r_s \), to be of the order of the small radius of a tokamak so about 1m, and some aspect ratio of order 1/3, this means \( \gamma_z \sim \gamma_q \). With these values, we end up with \( \langle v_z \rangle \sim \langle v_\theta \rangle \sim c/1000 \), \( c \) being the speed of light. And as well \( \gamma_z \sim \gamma_q \sim \beta(v) \sim 5 \times 10^{10} \text{USI} \) (corresponding to the international units, note \( \gamma_z \) and \( \gamma_q \) do not have the same dimensions but \( r \sim 1 \)). We can as well estimate the current \( I_z \sim 5 \times 10^5 \text{A} \). These estimations are in line with typical scales of parameters in magnetized fusion machines, we may thus anticipate that these stationary solution could be relevant in the fusion context, and especially the exhibited bifurcation.

IV. CONCLUSION AND PERSPECTIVES

In this paper we have computed a family of stationary solutions of the Vlasov-Maxwell equations, in a cylindrical geometry. These solutions correspond to a thermodynamic equilibrium and display a non-uniform density profile at equilibrium, with as well a non-uniform kinetic temperature profile, as soon as the plasma displays a collective motion on the poloidal or “toroidal” direction. This simple feature is already somewhat counter intuitive as the commonly accepted paradigm in tokamak physics is that these non-uniform profiles are the results of out of equilibrium features, with energy injection at the center and dissipation at the walls, so these solutions with global plasma momentum are offering a possibly different perspective on the confinement. As shown the solutions are obtained from applying an entropy maximization principle from which a probability density function is obtained, and then a self-consistent equation has to be solved on the vector potential using Maxwell-Ampère equation, that looks like a Poisson equations and ends up in solving two coupled nonlinear second order ordinary differential equations. The solutions are described using three intensive variables \( \beta, \gamma_z, \gamma_q \) corresponding to the Lagrangian multipliers related respectively to energy, momentum and angular momentum conservations. From these parameters a typical scale on which plasma confinement is observed \( r_s \), emerges and depends only on the ratio of \( \gamma_z \) and \( \gamma_q \), and is as such independent of the global temperature. Moreover, diamagnetic effects play an important role and a bifurcation between solutions showing an enhanced confinement profile from more regular one is displayed and the threshold computed. Finally, when the bifurcation is crossed and confinement is enhanced, there are regions in phase space where individual particles are subject to a double well potential exhibiting a separatrix. The presence of this separatrix in these enhanced confinement profile is consistent to what was previously anticipated in a non self-consistent setting [23] and are as well roots for Hamiltonian chaos under any perturbations, that can also break the magnetic moment conservation [29], and create some possible problems regarding the validity of gyrokinetic simulations.

Even though computed through a maximizing principle, the stability of these solutions under for instance a small perturbation like moving the system to a torus with a large aspect ratio is not at all given. A perspective of this work would then be to assess the stability of these solutions, to check also what happens near the separatrices regarding chaos and the breaking of the magnetic moment, when moving to a real toroidal geometry and the poloidal symmetry is lost.

Appendix A: Generalization to a two species system

with charges \( q^+ \) and \( q^- \), and mass \( m^+ \) and \( m^- \)

We derive below the full self-consistent system that give rise to a stationary solution of the Vlasov-Maxwell system. We follow the same path as the one used for only one species. We use the notation with \( a \) or \( a^- \), at the upper corner, to simplify the notations corresponding to each species, for example the test particles Hamiltonians write

\[
H^\pm = \frac{(p^\pm - q^\pm A)^2}{2m^\pm},
\]

(A1)

and then lead to the distributions functions.
\[ f^\pm = f_0^\pm e^{-\beta H - \gamma^\pm_\phi p^\pm_\phi - \gamma^\pm_\mu \hat{r}^\pm_\mu} \] (A2)

after Lagrange multipliers introduction and maximization of the entropy. Note that by doing so, we assume that the entropy is additive so the global maximum may be the sum of two maxima taken for each species individually, which neglect somehow the couplings through the current for instance, so this may not be an thermodynamic equilibrium in the end, but anyhow this leads to a stationary solution of the Vlasov-Maxwell system. We assume that each distribution is a stationary solution of the Vlasov so that

\[ \{ f^\pm, H^\pm \} = 0. \] (A3)

If we take \( a^\pm = \frac{\gamma^\pm_\phi}{2} \left( q^\pm B_0 - \frac{m^\pm \gamma^\pm_\mu}{2} \right) \), \( b^\pm = -q^\pm B_0 \hat{r}^\pm_\mu \), \( c^\pm = q^\pm B_0 \gamma^\pm_\phi \) and \( \gamma^\pm_\mu = -\frac{m^\pm (\gamma^\pm_\phi)^2}{2m^\pm} \), the normalization of each distribution function can be derived through

\[
N^\pm = \int f^\pm d^3 p^\pm d^3 q^\pm = f_0^\pm 4\pi^2 R \left( \frac{2\pi m^\pm}{\beta^\pm} \right)^{3/2} \int_0^{\infty} r e^{-a^\pm r^2 - b^\pm G(r) - c^\pm K(r) - \gamma^\pm_\mu \hat{r}^\pm_\mu} \, dr
\]

for \( N^\pm \) the numbers of particles. So the normalization of \( \rho^\pm \)

\[
\frac{f^\pm}{4\pi^2 R \left( \frac{2\pi m^\pm}{\beta^\pm} \right)^{3/2} \int_0^{\infty} r e^{-a^\pm r^2 - b^\pm G(r) - c^\pm K(r) - \gamma^\pm_\mu \hat{r}^\pm_\mu}}
\]

we can then compute the spatial densities for each species

\[
n^\pm(q) = \int f^\pm d^3 p^\pm = \frac{N^\pm}{4\pi^2 R \int_0^{\infty} r e^{-a^\pm r^2 - b^\pm G(r) - c^\pm K(r)} \, dr}
\]

and the charge radial density

\[
\rho^\pm(r) = q^\pm \int n^\pm(q) r \, d\theta \, dz = \frac{q^\pm}{\gamma^\pm} e^{-a^\pm r^2 - b^\pm G(r) - c^\pm K(r)}
\]

with \( \gamma^\pm = 4\pi^2 R \int_0^{\infty} r e^{-a^\pm r^2 - b^\pm G(r) - c^\pm K(r)} \, dr \). In order to move to self consistency, we as well compute, by component, the currents densities induced. Since

\[ v^*_z = \frac{1}{m^\pm} (p^*_z - q^\pm B_0 G(r)) \] (A8)

and

\[
v^*_\theta = \frac{1}{m^\pm} \left( \frac{p^*_\theta}{r} - q^\pm B_0 \left( \frac{r}{2} + \frac{1}{r} K(r) \right) \right),
\]

we obtain after integration \( \phi^\pm_\theta(q) \) and \( j^\pm_\theta(q) \), so the full current densities are given by

\[
J^\pm(r) = -\frac{1}{\beta^\pm} \left( \gamma^\pm_\phi r e_\theta + \gamma^\pm_\mu e_z \right) \rho^\pm(r).
\]

(A10)

Furthermore, we point out the relations

\[
\frac{j^\pm_\theta(q)}{r j^\pm_z(q)} = \frac{\gamma^\pm_\phi}{\gamma^\pm_\mu}.
\]

(A11)

We now move to the full self-consistent equation, we remain in Coulomb gauge \( \nabla \cdot A = 0 \), so we have

\[
\Delta A = -\mu_0 \left( J^+ + J^- \right)
\]

(A12)

and we end up with the self-consistent equation

\[
\begin{aligned}
\left\{ \begin{array}{l}
\frac{1}{\gamma^+} \left( \frac{1}{\gamma^+} \frac{\partial}{\partial r} K(r) \right) = \frac{\mu_0}{\beta^+} \left[ \frac{\gamma^+}{\beta^+} \rho^+(r) + \frac{\gamma^-}{\beta^-} \rho^-(r) \right] \\
\frac{1}{\gamma^-} \left( \frac{1}{\gamma^-} \frac{\partial}{\partial r} G(r) \right) = \frac{\mu_0}{\beta^-} \left[ \frac{\gamma^-}{\beta^-} \rho^+(r) + \frac{\gamma^+}{\beta^+} \rho^-(r) \right]
\end{array} \right.
\]

(A13)

We recall that we are assuming no electric field, so we have to impose electro-neutrality

\[
\rho^+(r) + \rho^-(r) = 0
\]

(A14)

that implies

\[
\begin{aligned}
\left\{ \begin{array}{l}
\frac{1}{\gamma^+} \left( \frac{1}{\gamma^+} \frac{\partial}{\partial r} K(r) \right) = \frac{\mu_0}{\beta^+} \left[ \frac{\gamma^+}{\beta^+} \rho^+(r) - \frac{\gamma^-}{\beta^-} \rho^-(r) \right] \\
\frac{1}{\gamma^-} \left( \frac{1}{\gamma^-} \frac{\partial}{\partial r} G(r) \right) = \frac{\mu_0}{\beta^-} \left[ \frac{\gamma^-}{\beta^-} \rho^+(r) + \frac{\gamma^+}{\beta^+} \rho^-(r) \right]
\end{array} \right.
\]

(A15)

We end up with a form of equations that are formally identical to the ones found in the case of a single species with neutralizing background:

\[
\begin{aligned}
\left\{ \begin{array}{l}
\frac{1}{\gamma^+} \left( \frac{1}{\gamma^+} \frac{\partial}{\partial r} K(r) \right) = \kappa_{\theta/z} e^{-a^+ r^2 - b^+ G(r) - c^+ K(r)} \\
\frac{1}{\gamma^-} \left( \frac{1}{\gamma^-} \frac{\partial}{\partial r} G(r) \right) = \kappa_{\theta/z} e^{-a^- r^2 - b^- G(r) - c^- K(r)}
\end{array} \right.
\]

(A16)

where

\[
\kappa_{\theta/z} = \frac{\mu_0}{B_0} \left[ \frac{\gamma^+}{\beta^+} - \frac{\gamma^-}{\beta^-} \right] q^+ N^+ = \frac{\mu_0}{B_0} \left[ \frac{\gamma^+}{\beta^+} - \frac{\gamma^-}{\beta^-} \right] q^+ \int_0^{\infty} r e^{-a^+ r^2 - b^+ G(r) - c^+ K(r)} \, dr
\]

(A18)
