A Wideband Generalization of the Near-Field Region for Extremely Large Phased-Arrays

Nitish Deshpande, Student Member, IEEE, Miguel R. Castellanos, Member, IEEE, Saeed R. Khosravirad, Member, IEEE, Jinfeng Du, Member, IEEE, Harish Viswanathan, Fellow, IEEE, and Robert W. Heath Jr., Fellow, IEEE

Abstract—The narrowband and far-field assumption in conventional wireless system design leads to a mismatch with the optimal beamforming required for wideband and near-field systems. This discrepancy is exacerbated for larger apertures and bandwidths. To characterize the behavior of near-field and wideband systems, we derive the beamforming gain expression achieved by a frequency-flat phased array designed for plane-wave propagation. To determine the far-field to near-field boundary for a wideband system, we propose a frequency-selective distance metric. The proposed far-field threshold increases for frequencies away from the center frequency. The analysis results in a fundamental upper bound on the product of the array aperture and the system bandwidth. We present numerical results to illustrate how the gain threshold affects the maximum usable bandwidth for the n260 and n261 5G NR bands.

Index Terms—Near-field, wideband, phased-array, frequency-selective, beamforming gain.

I. INTRODUCTION

Distinguishing between the near-field and far-field is becoming increasingly relevant as modern wireless devices begin to operate in both propagation regions. The most common near-field distance, known as the Fraunhofer distance, is proportional to the square of the aperture and inversely proportional to the wavelength [1]. To satisfy the data rate requirements of 5G and beyond, wireless systems have shifted to higher carrier frequencies and larger antenna arrays [2]. For these modern arrays, the Fraunhofer distance becomes comparable to the typical cell radius. For example, the Fraunhofer array distance for a uniform linear array (ULA) with 128 antennas and half-wavelength inter-antenna spacing operating at 28 GHz is around 88 m. This is a good fraction of the cell radius of an urban microcellular and picocellular deployment [3]. In the near-field, the phase variation over the array aperture is non-linear and is difficult to estimate with a phased-array using conventional beam-training procedures [2]. Hence, a uniformly-spaced phase shift technique based on far-field propagation with planar wavefronts is used in practice [1], [4]. The phase mismatch due to the inaccurate use of the far-field beamforming techniques can lead to beamforming gain losses that worsen as the array aperture increases [4], [5], [6].

Wideband systems with large arrays suffer from a phenomenon known as beam squint, i.e., the phase mismatch between the frequency-flat response of the phased-array and the frequency-selective response of the wideband channel. Moreover, array inter-symbol interference occurs for frequency-selective multipath channel because the propagation delay across a large array is non-negligible compared to the symbol duration [7]. This reduces the beamforming gain for frequencies away from the center frequency. This phase-mismatch can be corrected by replacing the frequency-flat phased-array with a frequency-selective beamformer. However, the implementation of a frequency-selective beamformer using a fully-digital space-time precoder [8] or an analog true-time-delay (TTD) architecture [9] is difficult for larger arrays due to high power consumption. For wideband phased-array systems operating in the near-field, the two phase mismatches due to far-field and narrowband system design jointly affect the beamforming gain. Hence, it is crucial to characterize this combined effect for the analysis of large phased-array wideband systems [6].

Near-field and wideband effects have generally been considered separately in the literature. Various near-field metrics have been proposed in prior work [10], [11]. The definition of the Fraunhofer array distance is based on the phase variation of a monochromatic wave over the array length [1]. In [10], the proposed near-field metric uses the amplitude variations to determine the far-field to near-field transition distance. The metrics in [1], [10] did not consider the angle of incidence and have assumed broadside incidence only. The effective Rayleigh distance incorporates the incidence angle in the beamforming gain analysis [11]. One common shortcoming of these methods is that the beamforming gain analysis is restricted only for a single frequency and not for a band of frequencies. Although [12], [13] analyzed the beamforming gain for wideband systems and incorporated the beam squint effect, they are based on the plane-wave approximation. To summarize, the existing work on the beamforming gain analysis either assumes a near-field and narrowband system [1], [10], [11] or a far-field and wideband system [12], [13].

In this letter, we analyze the beamforming gain of a multiple-input-single-output (MISO) communication system with a ULA at the transmitter for a general near-field and wideband channel with a beamformer based on the far-field and narrowband assumption. For a large number of antennas, the beamforming gain can be approximated with a closed-form expression. The derived expression can be generalized to arbitrary carrier frequencies and array sizes. We propose...
the bandwidth-aware-near-field distance (BAND) to characterize the far-field to near-field transition in a wideband system. The BAND increases for frequencies away from the center frequency, which implies that wideband systems have a larger near-field region. Expressing the system parameters as a function of the beamforming gain uncovers a tradeoff between the aperture and bandwidth.

Notation: A bold lowercase letter a denotes a vector, (·)* denotes conjugate transpose, |·| indicates absolute value, [a]n denotes the nth element of a, O(·) denotes the big O notation, $C(\gamma) = \frac{\lambda}{j} \cos(\frac{j}{2}d^2t)$ and $S(\gamma) = \int_0^\infty \frac{\pi}{2} \sin(\frac{j}{2}d^2t) dt$ denote cosine and sine Fresnel functions, inf{·} denotes the infimum.

II. SYSTEM MODEL

Let us assume a co-polarized single-user MISO communication system with an N antenna ULA at the transmitter and a single antenna at the receiver. All antennas are assumed to be isotropic. The transmitter is oriented along the x axis with inter-antenna spacing d. The x coordinate of the nth transmit antenna is defined as $d_n = 2n - N + 1$ d for $n = 0, 1, \ldots, N - 1$. The receiver location is assumed to be fixed at a distance $r$ from the transmit array center, i.e., the origin, and at an angle $\theta$ with the y axis. The receiver location is $(r \sin(\theta), r \cos(\theta))$. The distance between the receive antenna and the nth transmit antenna is $r_n = \sqrt{r^2 - 2rd_n \sin(\theta) + d_n^2}$.

For analytical purposes, we assume the channel to be a line-of-sight (LOS) path between the transmitter and receiver. The inclusion of non-line-of-sight (NLOS) components in a near-field communication system is a second-order effect and is ignored in this study. The LOS path can be characterized by the path loss and the path delay. The LOS path loss between all transmit antennas and the receive antenna is assumed to be the same and denoted by $G(r)$. This assumption is valid for $r \sim O(L^2)$ when $p > 1$, where $L = N d$ is the array aperture [14]. In this letter, the proposed BAND $\sim O(L^2)$ which will be proved in Section IV. Hence, it is appropriate to ignore path loss amplitude variations across the array. Let $\lambda_c$ denote the center frequency of the passband signal, $\lambda_c$ denote the center wavelength, and c denote the speed of light. The passband time-domain channel impulse response from the nth antenna is $h_b(t) |_n = \sqrt{G(r)} \delta(t - \frac{d_n}{c})$. The pseudo-complex baseband equivalent channel response after down-conversion is $h_b(t) |_n = \sqrt{G(r)} e^{-j2\pi \frac{d_n}{\lambda_c} \delta(t - \frac{d_n}{c})}$. The frequency-domain channel impulse response at baseband frequency $f$ is

$$h(f) |_n = \sqrt{G(r)} e^{-j2\pi \frac{d_n}{\lambda_c} (f + f_c)}.$$ (1)

The general channel response in (1) can be approximated under the narrowband and far-field assumptions. Under the narrowband assumption, the baseband frequency can be treated large, i.e., $f \approx 0$. Taking the series expansion of the channel phase response around $f \approx 0$, we have $\exp(-j2\pi \frac{d_n}{\lambda_c} (f + f_c)) = \exp(-j2\pi \frac{d_n}{\lambda_c} (f + O(f)))$. Under the far-field assumption, the distance $r$ can be treated large, i.e., $r \to \infty$. Taking the series expansion of the channel phase response around $r \to \infty$, we have $\exp(-j2\pi \frac{d_n}{\lambda_c} (f + f_c)) = \exp(-j2\pi \frac{(r - d_n \sin(\theta) + O\left(\frac{1}{r^2}\right))}{\lambda_c} (f + f_c))$. Combining both the expansions, we have $\exp(-j2\pi \frac{d_n}{\lambda_c} (f + f_c)) = \exp(-j2\pi \frac{(r - d_n \sin(\theta) + O\left(\frac{1}{r^2}\right))}{\lambda_c} (f + O(f)))$ when the narrowband and far-field assumptions both hold. Using the subscripts nf, ff, wb, and nb to denote near-field, far-field, wideband, and narrowband assumptions, respectively, we summarize the four channel models, for the $N \times 1$ channel vectors, $h_{nf,wb}(f)$, $h_{nf,nb}$, $h_{ff,wb}(f)$, and $h_{ff,nb}$, in Table I.

| Channel response | Expression |
|------------------|------------|
| $h_{nf,wb}(f)_n$ | $\sqrt{G(r)} e^{-j2\pi \frac{d_n}{\lambda_c} (f + f_c)}$ |
| $h_{nf,nb}$ | $\sqrt{G(r)} e^{-j2\pi \frac{d_n}{\lambda_c} f_c}$ |
| $h_{ff,wb}(f)_n$ | $\exp(-j2\pi \frac{d_n}{\lambda_c} f_c) (f + f_c)$ |
| $h_{ff,nb}$ | $\sqrt{G(r)} e^{-j2\pi \frac{d_n}{\lambda_c} f_c}$ |

III. BEAMFORMING GAIN ANALYSIS

We analyze the performance loss due to $f_{nf,nb}$ in terms of the normalized beamforming gain. The definitions of the normalized beamforming gains under different channel assumptions are summarized in Table II. The normalization is such that the maximum gain value is 0 dB. The beamforming gain $\mu_{ff,wb}(f)$ only captures the wideband effect and $\mu_{nf,nb}$ only captures the near-field effect.

We express the inner product in $\mu_{nf,wb}(f)$ as a summation of the complex phases over N antennas as $\frac{1}{\sqrt{N}} \sum_{n=0}^{N-1} e^{j\phi_n}$, where $\phi_n = -\angle(h_{nf,wb}(f) |_n) + \angle(h_{ff,nb} \phi_n)$. From the definition of $f_{nf,nb}$, $\phi_n = -\angle(h_{nf,wb}(f) |_n) + \angle(h_{ff,nb} \phi_n)$.

In the radiating near-field (Fresnel) region, i.e., $r_n > 0.62 \frac{d_n}{\lambda_c}$, the $O(\frac{1}{r_n})$ term in the expansion of $r_n = r - d_n \sin(\theta) + \frac{d_n^2 \cos(\theta)}{2r} + O(\frac{1}{r^2})$ can be ignored [15]. Hence, from Table I and expansion of $r_n$, we express $\phi_n \approx \frac{2\pi}{c} ((r - d_n \sin(\theta) + \frac{d_n^2 \cos(\theta)}{2r}) (f + f_c) - (r - d_n \sin(\theta)) f_c)$. To express $\phi_n$ in terms of dimensionless parameters, let the normalized distance be $\tilde{r} = \frac{r}{\lambda_c}$, the normalized inter-antenna spacing be $\tilde{d} = \frac{d_n}{\lambda_c}$, and the number of antennas be $\tilde{N} = \frac{N}{\lambda_c}$.
the normalized frequency be \( \bar{f} = \frac{f}{f_c} \). Hence, we express \( \phi_n \approx \phi_{n,\text{wb}} + \phi_{n,\text{f}} \), where \( \phi_{n,\text{wb}} = -\pi(2n - N + 1)\bar{d}\sin(\theta) \bar{f} \) and \( \phi_{n,\text{f}} = \frac{\pi(\bar{f}+1)d^2\cos^2(\theta)(2N-1)}{2} \). The expression for \( \mu_{n,\text{wb}}^{\text{approx}}(\bar{f}) = \left| \frac{1}{N} \sum_{n=0}^{N-1} \partial(\phi_{n,\text{wb}} + \phi_{n,\text{f}}) \right| \) depends only on the normalized parameters. Hence, this analysis is independent of the carrier frequency; the same beamforming gain can be obtained for different carrier frequencies provided that the normalized parameters remain fixed. The expression for the far-field wideband gain \( \mu_{n,\text{wb}}(\bar{f}) \) in [13] can be obtained by setting \( \phi_{n,\text{f}} = 0 \). The near-field narrowband gain \( \mu_{n,\text{nb}}(\bar{f}) \) can be obtained by setting \( \phi_{n,\text{wb}} = 0 \) and \( f = 0 \). In Lemma 1, we further simplify \( \mu_{n,\text{wb}}^{\text{approx}}(\bar{f}) \) to get an expression in terms of Fresnel functions whose arguments depend on the system parameters.

**Lemma 1:** The expression of \( \mu_{n,\text{wb}}^{\text{approx}}(\bar{f}) \) can be further approximated for large \( N \) with fixed \( d \) as

\[
G(\gamma_1, \gamma_2) = \lim_{N \to \infty} \mu_{n,\text{wb}}^{\text{approx}}(\bar{f}) = \left| \frac{\bar{c}(\gamma_1, \gamma_2) + j\bar{s}(\gamma_1, \gamma_2)}{2\gamma_2} \right|. \tag{2}
\]

\( \bar{c}(\gamma_1, \gamma_2) \equiv C(\gamma_1 + \gamma_2) - C(\gamma_1 - \gamma_2) \) and \( \bar{s}(\gamma_1, \gamma_2) \equiv S(\gamma_1 + \gamma_2) - S(\gamma_1 - \gamma_2) \), where \( \gamma_1 = -\tan(\theta)\bar{f}\sqrt{\frac{2\pi}{1+\bar{f}}} \), \( \gamma_2 = \bar{L}\cos(\theta)\sqrt{\frac{1+\bar{f}}{2\gamma_2}} \), and the normalized array aperture is \( \bar{L} = N\bar{d} \).

**Proof:** We rewrite \( \mu_{n,\text{wb}}^{\text{approx}}(\bar{f}) \) by defining \( \Delta_m = \frac{1}{N} \) for

\[
m = 0, 1, \ldots, N-1, \quad a = \cos(\theta)\sqrt{\frac{(1+\bar{f})d^2}{2}}, \quad b = \frac{1}{a}\left(\frac{1+\bar{f}}{2}\right)^2 \cos^2(\theta)(N-1) + \frac{d\sin(\theta)\bar{f}}{2} \tag{3}
\]

to get

\[
\mu_{n,\text{wb}}^{\text{approx}}(\bar{f}) = \left| \Delta_m \sum_{m=0}^{N-1} \exp\left(2\pi j(mN-b)\right) \right|. \tag{3}
\]

As \( N \to \infty \), we can express the summation in (3) as an integral using the Riemann integral method [4] as

\[
\mu_{n,\text{wb}}^{\text{approx}}(\bar{f}) = \left| \int_0^1 \exp\left(2\pi j(aNt-b)\right) dt + O\left(\frac{1}{N}\right) \right|. \tag{4}
\]

where (a) follows by letting \( aNt-b = \frac{t'}{d} \). For large \( N \), using \((N-1)d \approx (N+1)d \approx N\bar{d} = \bar{L} \), we get (2).

The purpose of this simplification is to establish a closed-form algebraic relationship between the system parameters and the beamforming gain threshold. Lemma 1 shows the relationship between the parameters, \( \{\bar{f}, \bar{r}, \bar{L}, \theta\} \), and a 2D parameter space defined by \( \gamma_1 \) and \( \gamma_2 \). The compression from four parameters to two new parameters \( \gamma_1 \) and \( \gamma_2 \) allows us to visualize the beamforming gain function. It also simplifies numerical simulations by varying \( \gamma_1 \) and \( \gamma_2 \) instead of varying four system parameters.

The expression derived in Lemma 1 simplifies to the narrowband case, i.e., \( \bar{f} = 0 \), by substituting \( \gamma_1 = 0 \) in (2). Hence, the near-field narrowband gain for large \( N \) is defined as \( G_{\text{nb}}(\gamma_2) = \lim_{N \to \infty} \mu_{n,\text{nb}} = \left| \frac{C(\gamma_2) + J(\gamma_2)}{2\gamma_2} \right| \), which is the same near-field gain expression derived in [4] and [11]. We have generalized \( G_{\text{nb}}(\gamma_2) \) [4], [11] by incorporating the bandwidth effect through the parameter \( \gamma_1 \).

The 2D cross-sections of the beamforming gain are shown in Fig. 1. In Fig. 1 (a), we keep \( \gamma_1 \) fixed and plot \( G(\gamma_1, \gamma_2) \) as a function of \( \gamma_2 \). Assuming a non-zero angle \( \theta \), the 2D plot corresponding to \( \gamma_1 = 0 \), shown in blue, represents the narrowband case which is same as the plot shown in prior work on near-field propagation [4], [11]. The parameter \( \gamma_2 \) captures the transition from far-field to near-field in [11]. The effective Rayleigh distance, \( d_{\text{ERD}}(\theta) = 0.367 \cos^2(\theta)(2L^2\lambda_c) \), is defined using \( \gamma_2 \) with \( f = 0 \), as the distance below which the value of the beamforming gain \( G_{\text{nb}}(\gamma_2) \) falls under the threshold 0.95 in linear scale [11]. We observe that for the wideband case, i.e., \( f \neq 0 \), the value of \( G(\gamma_1, \gamma_2) \) drops sharply with \( \gamma_2 \) as \( \gamma_1 \) increases. In Fig. 1 (b), \( \gamma_2 \) is fixed and we plot \( G(\gamma_1, \gamma_2) \) as a function of \( \gamma_1 \). For small values of \( \gamma_2 \), the peak value is close to 0 dB. However, for larger values of \( \gamma_2 \), the peak value drops and the main lobe shrinks. These results suggest that the joint effect of \( \gamma_1 \) and \( \gamma_2 \) is more severe than their individual effect.

The 2D cross-sections in Fig. 1 resemble the plots from existing work [11], [12], [13] that studies the wideband and near-field phenomena separately. The beamforming gain \( G(\gamma_1, \gamma_2) \) jointly models the wideband and near-field effects. We analyze the connections of \( \{\gamma_1, \gamma_2\} \) with \( \{f, \bar{r}, \bar{L}, \theta\} \) in Section IV.

### IV. Inverse Mapping of Beamforming Gain to System Parameters Space

Most of the existing studies [1], [10], [11], [12], [13] analyze the beamforming gain as a function of the different system parameters. From a system design perspective, however, it is essential to understand the inverse relationship for each system parameter as a function of the beamforming gain and other system parameters. We identify a fundamental tradeoff between the aperture and bandwidth in Section IV-A. We also establish a frequency-selective near-field boundary distance in Section IV-B.

#### A. Aperture–Bandwidth Product

In Section III, we introduced the beamforming gain dependence on \( f \) through \( \gamma_1 \) and \( \gamma_2 \). From Lemma 1, the normalized frequency \( f \) can be expressed as \( f = -\frac{\gamma_1}{\bar{L}\sin(\theta)} \). We also define the fractional bandwidth as \( f_B = |2\bar{f}| \). Hence, we have the relation

\[
|f_B\bar{L}\sin(\theta)| = 2|\gamma_1\gamma_2|. \tag{5}
\]

To understand the maximum limit up to which the aperture and/or bandwidth can be scaled while maintaining the narrowband and far-field assumption, we are interested in the maximum limit of the right hand side of (5) which can be found numerically for a given value of \( G(\gamma_1, \gamma_2) \).
We show the 2D contour plot of $G(\gamma_1, \gamma_2)$ in Fig. 2. The contour plot is defined as the locus of the points in the $(\gamma_1, \gamma_2)$ space which achieve a fixed value of the beamforming gain $G(\gamma_1, \gamma_2)$. The pair of hyperbolas marked in red, $|\gamma_1\gamma_2| = 0.16$, corresponds to $G(\gamma_1, \gamma_2) = -0.2$ dB. The pair of hyperbolas marked in blue, $|\gamma_1\gamma_2| = 0.12$, corresponds to $G(\gamma_1, \gamma_2) = -0.1$ dB. Hence, from (5) and Fig. 2, we conclude that to maintain a beamforming gain, $G(\theta, \gamma) \leq 0.1$ dB, $|f_L\sin(\theta)|$ must approximately lie in the range $[0.24, 0.32]$. The upper limit on $|f_L\sin(\theta)|$ decreases as the threshold increases. From a system design perspective, the maximum angle of incidence $\theta_{\max}$ can be chosen based on the sector division [16]. Hence, we get the worst case upper bound on $|f_L\sin(\theta)|$ and the array aperture, $L$, as

$$BL \leq \left| \frac{2c\gamma_1\gamma_2}{\sin(\theta_{\max})} \right|.$$  

The relationship in (6) plays an important role in determining the limits on the system design parameters for a particular beamforming gain. We define the maximum usable bandwidth, for a fixed aperture $L$, that achieves beamforming gain $\tau$, for the maximum incidence angle, as $B_{\max} = \frac{2c\gamma_1\gamma_2}{\sin(\theta_{\max})}$, where $\gamma_1\gamma_2|_{\max}$ is computed numerically for a given $\tau$. If the system bandwidth exceeds $B_{\max}$, the beamforming gain drops below the required threshold.

**Remark 1:** We observe that $f_LL$ can also be written as the ratio of the maximum propagation delay difference across the array to the symbol duration $T_s$, i.e., $f_LL = \frac{Nd/c}{T_s}$. In [7], the upper bound on $f_LL$ was loosely specified using $Nd/c \ll T_s$. The bound proposed in (6) is more precise.

**B. Bandwidth-Aware-Near-Field Distance (BAND)**

Using the relationship in Lemma 1, we propose a frequency-dependent near-field distance termed as BAND. The BAND is the smallest distance beyond which the beamforming gain is always above a certain threshold $\tau$. The definition of BAND is valid for $f \in (-\frac{B_{\max}}{2}, \frac{B_{\max}}{2})$. To compute the BAND, we propose a numerical procedure as follows.

1) Compute the set $T_1 = \{(\gamma_1, \gamma_2)|G(\gamma_1, \gamma_2) \geq \tau\}$ numerically. For example, the bright yellow region in the contour plot of Fig. 2 for $\tau \equiv -0.1$ dB.

2) Compute the set $T_2 = \{(\gamma_1', \gamma_2') \in T_1|\gamma_1'\gamma_2' = -f_L\sin(\theta)\}$.

3) Compute $B_{\text{BAND}} = \frac{L^2\cos^2(\theta)(1+f)}{2\gamma_2}$ where $\gamma_2 = \max\gamma_2'$ since the smallest value for distance is attained for the highest value of $\gamma_2'$.

Step 2 is essential in the BAND computation because it introduces the frequency dependency. For the narrowband case, step 2 is not required because $f = 0$. A closed form expression for BAND is obtained only at the center frequency. By setting $\tau = 0.95$ (or $-0.22$ dB) and $f = 0$, we get the same expression for the effective Rayleigh distance, $d_{\text{ERD}}$, which was derived in [11]. Similarly, by setting $\theta = 0$, $f = 0$, $\gamma_2 = 0.5$, we get the expression for the Fraunhofer array distance [1] as $d_{\text{FA}} = 2L^2\lambda_c$. A generalization of $d_{\text{FA}}$ is the direction-dependent Rayleigh distance [14], $d_{\text{DDRD}}$, which is also based on the maximum phase variation metric $\Delta\varphi(r, \theta)$. It is defined as the minimum link distance $r$ such that $\Delta\varphi(r, \theta) \leq \frac{\pi}{4}$. For a ULA, the expression for $\Delta\varphi(r, \theta)$ is given as $\Delta\varphi(r, \theta) = \max_{\gamma} \left[\frac{2\pi}{\lambda_c} \frac{d_2\cos^2(\theta)}{2f} \cdot \frac{\pi L^2 \lambda_c \cos^2(\theta)}{4r}\right]$. Hence, $d_{\text{DDRD}}(\theta) = 2L^2\frac{\lambda_c}{\sin(\theta)} \cos^2(\theta) = d_{\text{FA}} \cos^2(\theta) = \frac{d_{\text{ERD}}(\theta)}{2\sin(\theta)}$. The BAND is a wideband generalization of the near-field distances proposed in [1], [11], [14]. The BAND also determines the favorable regime for a transceiver hardware operating at any general frequency offset from $f_c$.

**Remark 2 (Comparison of BAND and $d_{\text{ERD}}, d_{\text{FA}}, d_{\text{DDRD}}$):** For a fixed $\tau$ (say 0.95 or $-0.22$ dB), let $d_{\text{ERD}}$ be expressed as $\lambda_c \frac{L^2\cos^2(\theta)}{2\gamma_2}$ ($\gamma_2 = 0.8257\pi$ for $\tau = 0.95$ [11]). For the wideband case, i.e., $f \neq 0$, let the BAND be expressed as $\lambda_c \frac{L^2\cos^2(\theta)}{2\sin(\theta)} (1 - \frac{\gamma_1\gamma_2}{L\sin(\theta)})$. The condition for BAND at $f \neq 0$ to be always greater than or equal to $d_{\text{ERD}}$ is given as $\frac{2\gamma_2}{\sin(\theta)} - 1 \leq 0$. Equality holds when $\gamma_1 = 0$ and $\gamma_2 = 2\gamma_2$. The parameters in Section V are chosen such that this condition is satisfied. Also, $B_{\text{BAND}} \geq 0.367d_{\text{DDRD}}(\theta)$ and $B_{\text{BAND}} \geq 0.367\cos^2(\theta)d_{\text{FA}}$.

**V. Numerical Results**

The analysis presented in Sections III and IV holds for any carrier frequency. In this section, we provide illustrations for some specific carrier frequencies currently used in the 5G standards [17].

In Fig. 3, $B_{\text{max}}$ is plotted as a function of the beamforming gain threshold for (a) $\theta_{\max} = \pi/6$ and (b) $\theta_{\max} = \pi/3$. For n261 band in 5G NR [17], $f_c = 28$ GHz. For the n260 band in 5G NR [17], we have $f_c = 39$ GHz. For each band, we plot $B_{\text{max}}$ for $N = \{64, 128\}$ and $d = \frac{\lambda_c}{2}$. We also mark the bandwidths of 200 MHz, 400 MHz, and 1.2 GHz.

Fig. 3 offers two important insights. For a given $\{L, f_c\}$ pair, we can determine the maximum possible beamforming gain for the 5G NR bandwidths. Conversely, we can also determine $B_{\text{max}}$ for a fixed value of beamforming gain. As expected from (6), for a fixed $f_c$, $B_{\text{max}}$ doubles as $L$ gets halved to maintain the same beamforming gain. Comparing Fig. 3(a) and Fig. 3(b), we demonstrate the tradeoff between $B_{\text{max}}$ and $\theta_{\max}$. In line with the result in (6), keeping remaining parameters fixed, $B_{\text{max}}$ reduces as $\theta_{\max}$ increases. In other words, less bandwidth is available when the angular coverage increases. In practice, $\theta_{\max}$ is based on the antenna coverage and sector division at the base station [16].

In Fig. 4, we show the contour plot in Fig. 2 with a change of variables from $(\gamma_1, \gamma_2)$ to $(r, f)$ space using Lemma 1.
Remark 2, the distance $d$ in the band. The distance $d$ yields a global minima at $f_c$.

for $d = 0.5$, $\theta = 60^\circ$, $f_c = 39$ GHz and for $N = 64$. Each contour denotes the BAND for a given gain threshold. For operating distances greater than the BAND, the beamforming gain will always remain above the threshold. The plot shows that the distance increases for frequencies away from the center frequency. This distance diverges beyond a certain value of frequency $|f|$, which illustrates the concept of the maximum usable bandwidth derived in (6). In Fig. 4, we also plot $d_{\text{ERD}}$, $d_{\text{DDRD}}$, and $d_A$, which are constant for all frequencies in the band. The distance $d_A$ is inaccurate because it does not incorporate the angle dependence and frequency-selectivity. Although both $d_{\text{DDRD}}$ and $d_{\text{ERD}}$ are angle dependent, $d_{\text{ERD}}$ is based on the beamforming gain, which is a better metric from a capacity perspective compared to the phase variation metric. The distance $d_{\text{ERD}}$ is consistent with the BAND value for $\tau = -0.22$ dB only at the center frequency 39 GHz because $d_{\text{ERD}}$ is derived using a narrowband model. In line with Remark 2, the distance $d_{\text{ERD}}$ underestimates the near-field distance for $f \neq 0$.

VI. CONCLUSION AND FUTURE WORK

In this letter, we proposed a new definition of the beamforming gain metric which incorporates both broadband and near-field propagation effects. For a MISO system with a ULA at the transmitter, we provided a simple closed-form expression for the beamforming gain in terms of standard Fresnel functions with two parameters that model the near-field and broadband effects. A key observation is that the beamforming gain depends only on the normalized frequencies and distances, which enables the validity of the insights for any carrier frequency. The proposed upper bound on the aperture-bandwidth product is useful for characterizing the performance of existing frequency-flat beamforming when scaling up in carrier frequency, bandwidth, and array aperture. We showed that the BAND corresponding to a fixed threshold attains minima at $f_c$ and increases for frequencies away from $f_c$.

The model and analysis presented in this letter are especially relevant for short distance transmission where the near-field effect is more relevant, with potentially small impact from angular spread. Analyzing impact of angular spread on beamforming gain is a second-order effect and out of the scope of the current work. The analysis of amplitude variations due to polarization mismatch in the near-field is a future research direction [10]. The expressions for BAND and aperture-bandwidth product can be extended to planar arrays and MIMO. This analysis is challenging because of the increase in number of system parameters compared to ULA and MISO model. Another research direction is performance analysis of dense arrays, which requires a circuit theoretic approach with proper modeling of frequency-selective mutual coupling. We also encourage the study of the aperture-bandwidth tradeoff for holographic metasurface antennas [5], [6] and TTD [9].
