Direct correlation functions (DCFs), linked to the second functional derivative of the free energy with respect to the one-particle density, play a fundamental role in a statistical mechanics description of matter. This holds in particular for the ordered phases: DCFs contain information about the local structure including defects and encode the thermodynamic properties of crystalline solids; they open a route to the elastic constants beyond low temperature expansions. Via a numerical tour de force we have explicitly calculated for the first time the DCF of a solid: based on the fundamental measure concept we provide results for the DCF of a hard sphere crystal. We demonstrate that this function differs at coexistence significantly from its liquid counterpart – both in shape as well as in its order of magnitude – because it is dominated by vacancies. We provide evidence that the traditional use of liquid DCFs in functional Taylor expansions of the free energy is conceptually wrong and show that the emergent elastic constants are in good agreement with simulation-based results.

Introduction. – In classical and quantum theories of many–body systems, two–point correlation functions or propagators play a very important role. In homogeneous systems, they describe the fundamental structural correlations; they can be interpreted as the probability of finding two particles at two different points (in general, these are points in space and time). In functional formulations of many–body theory, these two–point functions are generally related to functional derivatives of a generating functional with respect to two local source terms. In classical systems in equilibrium [1], the generating functional may be taken as the grand potential \( \Omega \) or aggregate states of classical systems thus entails knowing the structural order of these phases and constitutes a desirable scientific asset. In past decades, the total pair and direct correlations of simple and complex liquids have been studied in detail and qualitative and quantitative aspects of them are known [2]. In contrast, this is not the case for the crystalline state whose ordered nature is frequently only characterized by the periodicity in \( \rho(r) \) (which is the first derivative \( -\beta \delta\Omega / \delta \psi(r) \)). Here, we aim to close this knowledge gap on the DCF and demonstrate that the shape of a crystal DCF is very different from a liquid DCF and, in particular, is divergent in the limit of an ideal, defect-free crystal. Furthermore, we analyze (generalized) elastic constants, viz. thermodynamic derivatives with respect to density and strain, in terms of the crystal DCF and show that it encodes the mechanical properties.

Basic concepts. – The appropriate functional expansion of the excess part (over ideal gas) of the free energy around a reference bulk state with density \( \rho_0 \) is given by [1]:

\[
F^\text{exc}[\rho] = F^\text{exc}(\rho_0) + \int \! d\mathbf{r} \mu^\text{exc}(\mathbf{r}; \rho_0) \Delta \rho(\mathbf{r}) - \frac{1}{2 \beta} \int \! d\mathbf{r}_1 \int \! d\mathbf{r}_2 \ c(\mathbf{r}_1, \mathbf{r}_2; \rho_0) \Delta \rho(\mathbf{r}_1) \Delta \rho(\mathbf{r}_2) + \ldots
\]

(1)

Here, \( F^\text{exc}(\rho_0) \) is the excess part of the free energy of the reference state. For a liquid, \( \rho_0 \) is constant and \( \mu^\text{exc} \) is the constant excess chemical potential while for a crystal, \( \rho_0 \) and \( \mu^\text{exc} \) are lattice–periodic. \( c(\mathbf{r}_1, \mathbf{r}_2; \rho_0) \) is the
DCF of the reference state. In many theoretical works the classical solid is considered as a perturbation of the homogeneous liquid. In Eq. (1) this amounts to approximate $c(r_1, r_2; \rho_0) \approx c_{\text{liq}}(|r_1 - r_2|; \rho_0)$ with the translation invariant DCF of the liquid. Minimizations of such a liquid-like free energy functional can qualitatively (e.g. hard sphere systems [3]) and for some systems also quantitatively (e.g. soft systems [14]) describe crystals with a periodic $\rho(r)$, the underlying assertion is, however, that the crystal DCF is liquid-like.

Earlier fundamental considerations [7] cast doubts on this approach but actual evaluations of the crystal DCF were restricted to a harmonic model. For a density distribution $\rho(r)$ with lattice periodicity, the Fourier modes are discrete, nonzero only for reciprocal lattice vectors (RLV) $g$. The corresponding crystal DCF $c^{\text{cr}}(r_1, r_2)$ is invariant with respect to a global translation by a lattice vector $L$, i.e. $c^{\text{cr}}(r_1 + L, r_2 + L) = c^{\text{cr}}(r_1, r_2)$. We can define center-of-mass and relative coordinates by $s_{12} = \gamma_1 + \gamma_2 r_2$ and $r_{12} = r_1 - r_2$ (here, $\gamma = (1 - \gamma')$ is arbitrary). Thus the crystal DCF possesses an expansion [11, 8]

$$c^{\text{cr}}(r_1, r_2) = \sum_g \int \frac{dk}{(2\pi)^3} e^{i g \cdot s_{12}} e^{i k \cdot r_{12}} \hat{c}^{\text{cr}}_g(k),$$

which defines the RLV modes $\hat{c}^{\text{cr}}_g(k)$ of the DCF, where $\hat{c}^{\text{cr}}_g = 0 (k)$ is the Fourier transform of a translationally invariant $c(|r_1 - r_2|; \rho_0)$. Eq. (1) with $c(r_1, r_2) \approx c_{\text{liq}}(|r_1 - r_2|)$ fails fundamentally in considering exclusively this term. Later work pointed out the importance of non-liquidlike parts in the DCF to explain the occurrence of liquid–fcc [face centered cubic] vs. liquid–bcc [body centered cubic] transitions [8]. The non-liquidlike parts in a restricted expansion have been evaluated using liquid-state methods [10].

There are further arguments showing that the approximation of crystal DCF’s by their liquid counterparts should be considered conceptually wrong. The functional definition of $C$ entails that $C(r_1, r_2) = \partial^2 \rho(r_1)/\partial \rho(r_2)$ and describes the change in chemical potential at one point upon change of density at another point. Solids of particles with repulsive cores usually have very few vacancies (their relative concentration $n_{\text{vac}} \sim 10^{-4}$). It can be shown that for a bulk solid of hard spheres $\psi(r) = \beta \mu \propto -\ln n_{\text{vac}}$, i.e. it diverges for an ideal, defect-free crystal. A local change in density of the crystal should mainly be affected through a change in $n_{\text{vac}}$ and thus we expect the value of the DCF $O(c^{\text{cr}}) \sim 1/n_{\text{vac}} \approx 10^4$, about two orders of magnitude larger than the DCF of the hard sphere liquid. Moreover, according to Eq. (1), changes in free energy upon small density changes in the solid through deformations should be describable with just the crystal DCF at the reference point. This entails a relationship of all the elastic constants to $c^{\text{cr}}$. Therefore, the correct nature of the crystalline DCF should also be reflected in measurable quantities.

Direct correlation function from FMT. Below we analyze the crystal DCF of hard spheres with a density functional from Fundamental Measure Theory (FMT), currently the most accurate density functional theory available. The so-called dimensional crossover route of derivation of these FMT functionals [12] entails that the free energy of highly localized density profiles is exact. This is crucial for the description of crystals where the density is sharply peaked at lattice sites.

In FMT, the excess free energy is described by a local functional in a set of weighted densities (labeled by $\alpha$), $n_\alpha(r) = \int dr_1 \rho(r - r_1) w_\alpha(r_1)$ with $w_\alpha(r)$ being a corresponding weight function defined by geometrical characteristics of the particles [14]:

$$\beta \mathcal{F}^{\text{exc}}[\rho] = \int dr \Phi(n_\alpha(r)),$$

Here we use the White-Bear-II (WBII) tensorial version [13, 16] for $\Phi$ (the full definition is given in the SI). Crystal density distributions, the equation of state of both liquid and crystal and consequently the coexistence densities of the liquid and solid are in excellent agreement with simulations [11]. The crystal DCF follows from the second functional derivative of $\mathcal{F}$ with respect to $\rho$

$$c^{\text{cr}}(r_1, r_2) = -\sum_{\alpha \beta} \int dr \frac{\partial^2 \Phi(r)}{\partial n_\alpha \partial n_\beta} w_\alpha(r - r_1) w_\beta(r - r_2),$$

which can most conveniently be analyzed in reciprocal space; see the SI. We determine $c^{\text{cr}}$ by two different ways, on the one hand from the RLV expansion of an fcc lattice and, on the other hand (as a cross-check), via brute force six-dimensional Fourier transformation, both at the WBII melting point: packing fraction $\eta = 0.545$ and $n_{\text{vac}} = 2.18 \times 10^{-5}$.

Results are shown in Fig. 1. Panel (a) shows $c^{\text{cr}}(0, \Delta r)$, where the first point (origin) is a lattice point and $\Delta r$ points in (111) direction of the fcc cubic unit cell. The number $n$ of RLV shells considered (see the legend) demonstrates the slow convergence of the RLV expansion (we used up to $n = 10^4$ RLV shells) towards the result obtained from the brute force FT. The translationally invariant RLV mode $\hat{c}^{\text{cr}}_{g=0}(n = 0)$ describes the direct correlations with the center-of-mass variable averaged over the unit cell. It has a similar shape as the fluid DCF but is more than a factor 500 larger (note the separate axis scale for the fluid DCF in Fig. 1(a)). The shape of the full result is however very different from the fluid DCF. Fig. 1(b) shows $c^{\text{cr}}(0, \Delta r)$ using the RLV expansion and the brute force FT in the directions of (100), (110) and (111). These results demonstrate that the DCF is fairly isotropic around a lattice point. In contrast, the isotropy is lost if an interstitial point is chosen as the first point, see Fig. 1(c) which shows $c^{\text{cr}}(r_1, r_1 + \Delta r)$ in the
three directions with $r_1 = (\frac{a}{2}, \frac{a}{2}, \frac{a}{2})$ ($a$ is the side length of the cubic unit cell). Overall, the order of magnitude for $O(c^{\text{cr}}) \sim 10^3$ agrees very well with the estimate $1/n_{\text{vac}}$ from above, and the 3D spatial dependence is very different from a liquid DCF.

Elastic constants.– The calculation of macroscopic properties of a crystal from first principles requires a correct description of the microscopic structure. Having done the first step we can explore the ramifications of the discussed DCF properties for the elastic constants (we call this the DCF route to elastic constants). This has been done so far by using the fluid DCF only \[17-20\]. The familiar elastic constants are defined through an expansion of the free energy $F(\eta)$ of a strained crystal to second order in the Lagrangian strain tensor $\eta_{\alpha\beta} = (u_{\alpha\beta} + u_{\beta\alpha} + u_{\gamma\alpha}u_{\gamma\beta})/2$ where $u_{\alpha\beta}$ is the usual gradient of the displacement field ($u_{\alpha\beta} = \nabla_\beta u_\alpha$) and like indices are summed over \[21\]

$$F(\eta) \approx \frac{F(0)}{V} - p \eta_{\alpha\beta}\delta_{\alpha\beta} + \frac{1}{2} C_{\alpha\beta\gamma\delta} \eta_{\alpha\beta}\eta_{\gamma\delta}. \quad (5)$$

Here, $V$ is the volume of the unstrained equilibrium reference state with pressure $p$ and the number of particles is fixed. For an fcc crystal, there are only 3 independent elastic constants which in Voigt notation are $C_{11} = C_{\alpha\alpha\alpha\alpha}$, $C_{12} = C_{\alpha\alpha\beta\beta}$, $C_{44} = C_{\alpha\beta\alpha\beta}$ (no summation and $\alpha \neq \beta$). Since a free energy change to second order in strain is equivalent to a change in second order in the density profile (see Eq. \[1\]), the elastic constants should be expressible with just the density profile and the DCF at the reference state. For the change in density $\delta \rho (\mathbf{r})$ upon applying a linear displacement field $\mathbf{u} (\mathbf{r})$ and a change in average density $\delta \bar{\rho}(\mathbf{r})$ one may write \[22\]

$$\delta \rho (\mathbf{r}) \approx - \mathbf{u} (\mathbf{r}) \cdot \nabla \rho (\mathbf{r}) + \rho (\mathbf{r}) \frac{\delta \bar{\rho}(\mathbf{r})}{\bar{\rho}}. \quad (6)$$

While the density profile $\rho (\mathbf{r})$ varies rapidly on the length scale of the lattice spacing, the coarse grained displacement and average density field only exhibit smooth variations. This ansatz corresponds to an affine deformation of the crystal density profile. The change in average density $\bar{\rho}$ is the sum of two effects: the change in vacancy concentration (or occupancy of the unit cell) and the change of the unit cell volume \[23-24\]. Using this affine approximation, Refs. \[8-25\] decomposed the second order change in total free energy

$$\Delta F^{(2)} = \frac{1}{2 \beta} \int d\mathbf{r}_1 \int d\mathbf{r}_2 \left( \frac{\delta (\mathbf{r}_1 - \mathbf{r}_2)}{\rho (\mathbf{r}_1)^2} - c^{\text{cr}} (\mathbf{r}_1, \mathbf{r}_2) \right) \times \delta \rho (\mathbf{r}_1) \delta \rho (\mathbf{r}_2)$$

$$= \frac{1}{2} \int d\mathbf{r} \left( \lambda_{\alpha\beta\gamma\delta} \delta u_{\gamma\alpha} \delta u_{\delta\beta} - 2 \mu_{\alpha\beta} \delta \bar{\rho} u_{\beta\alpha} + \nu \left( \frac{\delta \bar{\rho}}{\bar{\rho}} \right)^2 \right). \quad (7)$$

This defines the generalized elastic constants as thermodynamic derivatives

$$\lambda_{\alpha\beta\gamma\delta} = \frac{1}{2} \hat{I} \left( \nabla_\alpha \rho (\mathbf{r}_1) \nabla_\beta \rho (\mathbf{r}_2) \right) c^{\text{cr}} (\mathbf{r}_1, \mathbf{r}_2, r_{12,\gamma} r_{12,\delta}),$$

$$\mu_{\alpha\beta} = \hat{I} \left( \rho (\mathbf{r}_1) \nabla_\alpha \rho (\mathbf{r}_2) c^{\text{cr}} (\mathbf{r}_1, \mathbf{r}_2, r_{12,\beta}),ight),$$

$$\nu = \hat{I} \left( \rho (\mathbf{r}_1) \left( \frac{\delta (\mathbf{r}_{12})}{\rho (\mathbf{r}_2)} - c^{\text{cr}} (\mathbf{r}_1, \mathbf{r}_2) \right) \rho (\mathbf{r}_2) \right) \quad (8)$$

where the integral operator $\hat{I} = \frac{1}{\sqrt{\beta}} \int d\mathbf{r}_1 d\mathbf{r}_2$ and $\mathbf{r}_{12} = \mathbf{r}_1 - \mathbf{r}_2$ with Cartesian components $r_{12,\alpha}$. According to Eq. \[6\], these generalized elastic constants have the following meaning: the $\lambda$‘s are the constants sensitive to a second–order density profile variation due to a combination of “strain–strain”, the $\mu$‘s accordingly are sensitive to “strain–average density change” and $\nu$ is sensitive to the combination “average density change–average density change”. It follows that for a defect–free crystal ($n_{\text{vac}} \rightarrow 0$) some of the generalized coefficients must become very large since in such a case an independent

FIG. 1: Direct correlation function $c^{\text{cr}} (\mathbf{r}_1, \mathbf{r}_2; \rho (\mathbf{r}))$ from FMT as function of distance (with $\sigma$ the sphere diameter) in a hard sphere fcc crystal at the melting density ($\eta = 0.545$); the vacancy concentration is $n_{\text{vac}} = 2.18 \times 10^{-5}$. (a) $c^{\text{cr}}$ in the RLV expansion up to $10^4$ shells; $\Delta r$ is started from a lattice site. The black solid line is from the brute force FT and the red dotted line is the fluid DCF \[13\] at $\eta = 0.545$ with scale on the right side. (b) $c^{\text{cr}} (0, \Delta r)$ in three directions by the brute force FT (solid line) and RLV expansion up to $10^4$ shells (dots). (c) $c^{\text{cr}} (\mathbf{r}_1, \mathbf{r}_1 + \Delta \mathbf{r})$ with distance measured from the interstitial point $\mathbf{r}_1 = (\frac{a}{2}, \frac{a}{2}, \frac{a}{2})$ and $a$ the side length of the cubic unit cell, lines are as in (b).
Generalized elastic constants ($kT\sigma^3$) 

![Graph](image)

**FIG. 2:** DCF route to elastic constants: (a) Generalized elastic constants and (b) Voigt elastic constants at coexistence ($\eta = 0.545$) as a function of vacancy concentration. Symbols connected with full lines are results from Eqs. (8) and (9), and dotted lines use Eqs. (8) and (9) with $c^{cf}(r_1, r_2) \rightarrow c^{lin}(|r_1 - r_2|; \eta_0)$, the fluid DCF at $\eta_0 = 0.545$.

variation of strain or average density would always be accompanied with a creation of interstitials whose free energy cost is large [26].

The standard elastic constants in Voigt notation are a suitable combination of the generalized constants reflecting the process of stressing the crystal without the constraint of fixed density (see the SI):

$$
C_{11} = \lambda_{xxxx} + 2\mu_{xx} + \nu + p
$$

$$
C_{12} = 2\lambda_{xxyy} - \lambda_{xxxx} + 2\mu_{xx} + \nu - p
$$

$$
C_{44} = \lambda_{xxyy} + p
$$

(9)

with $p$ the pressure. Note that Eq. (9) also requires to pass from linear to Lagrange strain [21] and that the volume of the DFT integration in Eq. (7) differs from the volume of the reference state used in Eq. (5).

The computation of the (generalized) elastic constants using the RLV modes of the FMT functional is described in the SI. To first establish their dependence on vacancy density, we employ a constraint minimization of the FMT functional fixing $n_{vac}$ [11]. In Fig. 2(a), the generalized elastic constants are shown for different $n_{vac}$ at coexistence ($\eta = 0.545$). Except for $\lambda_{xxyy}$, these are $\propto 1/n_{vac}$ in agreement with our reasoning above. $\lambda_{xxyy}$ is comparably small and insensitive to changes in $n_{vac}$. As it describes the response to shear strains which do not generate defects, i.e., do not create interstitials, this result also agrees with our expectation. Note that an evaluation of the generalized elastic constants by using a liquid–like DCF in Eq. (5) gives results almost independent on vacancy concentration; see the dotted lines in Fig. 2(a). Clearly, a fluid DCF qualitatively fails to describe the thermodynamic derivatives approaching the ideal crystal limit.

Interestingly, the Voigt elastic constants from the DCF route (Eq. (11), see Fig. 2(b)) remain almost unchanged for $n_{vac}$ up to $10^{-2}$, as a result of a delicate cancellation between the generalized elastic constants which vary from $10^4$ to $10^2$. The insensitivity of the elastic constants to local defects explains why previous calculations of the Voigt constants using a liquid–like DCF gave qualitatively reasonable behavior. Yet, quantitatively, the liquid DCF gives values off by a factor of 2, see the dotted lines in Fig. 2(b).

Additionally, we compare the Voigt elastic constants from the DCF route with the ones obtained by an explicit free energy determination of suitably deformed unit cells and using Eq. (5). For the choice of deformations, we follow the procedure proposed in Ref. [27] (see the SI for details) and perform a free minimization of the free energy without resorting to density profile parameterizations. In view of the high accuracy of the free energy for equilibrium crystals [11], this should constitute a reliable benchmark. The elastic constants can be grouped into combinations where the fcc crystal is compressed, viz., the bulk modulus $\frac{1}{2}C_{11} + \frac{2}{3}C_{12}$, and where it is not, $C_{11} - C_{12}$ and $C_{44}$. In Tab. I results from the DCF route and from explicit deformations in FMT are shown and compared with simulations [26] at the melting point. For all constants, values at least two orders of magnitude smaller than the defect-dominated strain derivatives are found, and results obtained from the FMT functionals by the two different routes are rather consistent with the simulation data. Differences are largest for the bulk modulus which apparently changes most during the nonaffine relaxation of the free energy; see the SI for an explicit calculation. The differences between the two routes point to necessary corrections to the affine approximation of the density profile change in Eq. (6), which is currently under investigation.

**Outlook.**—In this work, we have investigated the direct correlation function of the hard sphere solid using state–of–the–art density functionals of FMT type. The
crystal DCF is fundamentally different from the one of the hard sphere liquid as density changes require local defects, viz. vacancies, in solids which are close to ideal. The order of magnitude of the DCF is thus proportional to the inverse vacancy concentration. Defects, viz. vacancies, in solids which are close to ideal. The sensitivity of the generalized elastic constants to defect concentrations including in the ideal crystal limit. The sensitivity of the generalized elastic constants to defect concentrations suggests to have a closer look at defect–rich systems in the future such as polydisperse hard spheres (where interstitials will dominate over vacancies [28]), systems of colloidal cubes [29], or interpolating systems to defect-dominated cluster crystals [4]. We anticipate that the generalized constants play a role for solids with impurities and are relevant to mechanochemical coupling in such systems [30].
