I. INTRODUCTION AND MOTIVATION

When a surface of sand is exposed to wind or water flow, patterns like ripples or dunes are commonly formed. The physics of this process is extremely complex because it involves the interaction of a granular medium with a possibly turbulent hydrodynamic flow. It is therefore desirable to develop simplified models that capture some of the key features of the pattern formation.

In this paper we are concerned with a class of models which focus on the role of the mass transfer in the evolution of the pattern. Along a one-dimensional cut perpendicular to the ripples, the pattern is described by a set \( \{ \lambda_i \} \) of ripple lengths, where the index \( i \) labels the ripples in the array. The \( \lambda_i \) are used here as a general measure of ripple size, without reference to the detailed geometry of individual ripples (see Fig. 1). In particular, we do not distinguish between the linear size of a ripple and the mass it contains (for further discussion of this point see [2]).

During the evolution of the patterns, the flow transfers mass between neighboring ripples. The central assumption of the model is that the mass transferred to ripple \( i \) from ripple \( i+1 \) or \( i-1 \) (per unit time) is a function \( \Gamma(\lambda_i) \) of the size of the ripple which gains the mass. Further motivation for this assumption will be given below. We refer to \( \Gamma(\lambda) \) as the robber function [2].

Depending on the characteristics of the flow, the mass transfer between ripples can be symmetric or asymmetric. In the symmetric case the balance between loss and gain processes for a given ripple leads to the evolution equation [3]

\[
\frac{d\lambda_i}{dt} = \frac{1}{2} [ -\Gamma(\lambda_{i-1}) + 2\Gamma(\lambda_i) - \Gamma(\lambda_{i+1}) ],
\]

while in the asymmetric case (assuming, say, mass transfer only to the left) one has

\[
\frac{d\lambda_i}{dt} = -\Gamma(\lambda_{i-1}) + \Gamma(\lambda_i).
\]

The factor \( 1/2 \) in Eq. (1) makes the time scales for both the dynamics equal.

A homogeneous state of equally sized ripples, \( \lambda_i \equiv \bar{\lambda} \), is stationary under (1) and (2), but its stability depends on the derivative of the robber function: The pattern is stable for \( \Gamma'(\bar{\lambda}) < 0 \) and unstable for \( \Gamma'(\bar{\lambda}) > 0 \). In the unstable case the dominant mode is a modulation of period 2, in which every second ripple grows and every second one shrinks. As the size of the shrinking ripples reaches zero in a finite time, the evolution equations (1) and (2) have to be supplemented by an extinction rule: When the size of a ripple vanishes, it is removed from the system and the remaining ripples are relabeled such that the previous neighbors of the removed ripple become neighbors of each other. Extinction events contribute to the coarsening of the pattern, i.e., to an increase of the mean wavelength. In this work the reverse process

of ripple creation is not considered, hence coarsening is irreversible.

The symmetric mass transfer model \([1]\) was first proposed as a description of vortex ripples in coastal waters, which are created under the oscillatory flow of surface waves \([2]\). In that context the dependence of the robber function on the size of the gaining ripple is motivated by the observation that the mass transfer is effected mostly by a separation vortex which appears in the wake of that ripple. Numerical simulations \([3]\) and experiments \([3]\) show that \(\Gamma(\lambda)\) is nonmonotonic, with a maximum near \(\lambda = a\), where \(a\) is the amplitude of the fluid oscillations. Thus patterns of wavelength \(\lambda < a\) (\(\lambda > a\)) are unstable (stable), and the main interest is in the wavelength selection process starting from a short wavelength, unstable state \([2, 3]\).

A related, asymmetric mass transfer model for wind-driven sand ripples was introduced in \([3]\). The basic hypothesis of the model is that wind ripples wander with a speed that is inversely proportional to their size. This implies that a leading ripple (ripple \(i + 1\)) is eroded by the trailing ripple (ripple \(i\)) at a rate which is proportional to \(1/\lambda_i\), so the resulting evolution equation is of the type \([2]\) with \(\Gamma(\lambda) \sim 1/\lambda\). Since \(\Gamma'(\lambda) < 0\), the homogeneous pattern is stable. However, when fluctuations are included by discretizing the ripple sizes and implementing a stochastic mass transfer rule, a fluctuation-driven coarsening mechanism becomes effective and leads to an increase of the mean wavelength with time \(t\) as \(\ln t\).

In this article we consider a class of stochastic models whose noiseless counterparts are described by \([1]\) or \([3]\). We concentrate on monotonic, algebraic robber functions \(\Gamma(\lambda) \sim \lambda^\gamma\) and study the coarsening process regarding \(\gamma\) as a variable parameter. For \(\gamma < 0\) this extends the results of \([3]\) on fluctuation-driven coarsening. The case \(\gamma > 0\) is a simple realization of linearly unstable ripple evolution, and it is studied here as a first step towards a better understanding of models with nonmonotonic robber functions \([2, 3, 4]\). Although the models are defined using the terminology of sand ripples, they are connected to other problems in nonequilibrium statistical physics. For example, for \(\gamma = 0\) the system maps to coalescing random walks and is therefore exactly solvable. Other equivalences include exclusion processes, zero range processes, urn models, and cluster-cluster aggregation.

Our main results are the following. In general, one can identify two time scales in the dynamics: The one of ripple extinctions and the other at which the system would equilibrate to a steady state in the absence of extinctions. For \(\gamma < 0\) the loss of a ripple is a rare fluctuation when the mean ripple size is large. Therefore the two time scales are well separated, and the system has time to relax to a quasi-steady state between ripple extinctions. We show that this state is characterized by a product measure. This justifies the mean field assumption made in \([3]\), and allows us to calculate the stationary ripple size distribution. The product measure becomes exact only at the limit \(t \to \infty\) as the correlations in the system decay as a power law. The average ripple size grows logarithmically at late times, with a prefactor \(-\gamma^{-1}\).

For \(\gamma > 0\) extinctions are frequent events which occur on the same time scale as the evolution of the surviving ripples. We find in this case that the noise is irrelevant, so that the dynamics can be described by \([1]\) and \([2]\). For \(0 < \gamma < 1\) the mean ripple size grows algebraically with the exponent \(1/(1-\gamma)\), while the growth is exponential for \(\gamma = 1\). In the latter case the evolution equations become linear, and the problem can be solved exactly on the mean field level. The mean field theory reproduces the exponential growth for the mean ripple size, but incorrectly predicts a dependence of the ripple size distribution and the coarsening law on the initial conditions.

In the next section the model is introduced and its relations to other models are discussed. Algebraically decaying robber functions \((\gamma < 0)\) are considered in Sec. \(\text{II}\). The product form of the mass distribution is derived in Sec. \(\text{III A}\) the coarsening law is calculated in Sec. \(\text{III B}\), and the approach to the product measure is analyzed in Sec. \(\text{III C}\). Section \(\text{IV}\) is devoted to algebraically growing robber functions \((\gamma > 0)\). The mean-field theory is first developed for \(\gamma = 1\) and then compared to simulations (Sec. \(\text{IV A}\)). Section \(\text{IV B}\) examines the case \(0 < \gamma < 1\).

Conclusions and open questions are formulated in Sec. \(\text{V}\).

II. THE STOCHASTIC RIPPLE MODEL

A. Definition and simulation algorithm

In the stochastic model a sand ripple is characterized by its mass \(m\). The mass variables are integers such that each ripple consists of \(m_i\) elementary mass units and occupies a site \(i\) on a one-dimensional lattice. The mass is conserved, \(i.e., M := \sum_i m_i = \text{const.}\). The \(m_i\) correspond to the length variables \(\lambda_i\) used in equations \([1]\) and \([2]\). As mentioned in the Introduction, the mass and the length of ripples are here considered to be indistinguishable. We use different symbols for two reasons. We want to make a clear distinction between (i) the real and integer valued ripple sizes and (ii) between the deterministic and noisy dynamics.

Ripples interact only by exchanging mass with their nearest neighbors with an algebraic mass transfer rates \(\Gamma(m) = \Gamma_0 m^\gamma\). Since the constant \(\Gamma_0\) affects only the time scale it will be set equal to unity from now on. If ripples obtain mass only from one of their neighbors, say, from the right one, the mass transfer is called (totally) asymmetric. If the mass comes from both neighbors we call the dynamics symmetric. As was discussed in Sec. I, the asymmetric mass transfer naturally arises in the case of wind ripple formation \([3]\) whereas the symmetric dynamics takes place for ripple patterns forming under an oscillatory flow \([2]\).

In addition the model includes the removal of ripples
when their mass becomes zero. This is done such that lattice sites containing no mass are eliminated from the system. In this way each ripple always has a neighbor from which it can gain mass. If we denote the number of lattice sites at time $t$ by $N(t)$, the average ripple mass is $\langle m \rangle(t) = M/N(t)$.

In the simulations three different initial conditions are used. As random initial conditions we denote the case in which the probability to have a ripple of size $m$ is given by the geometric distribution $(1 - q)q^{m-1}$, with $0 < q < 1$. The probability $q$ is related to the mean ripple size as $\langle m \rangle = (1 - q)^{-1}$. A distribution $m_i = \langle m \rangle \forall i$ is referred to as monodisperse. The third possibility is a Poisson distribution.

The dynamics is implemented as follows. First a ripple is selected randomly and time is incremented by $N(t)^{-1}\Gamma_{\text{max}}^{-1}$, where $\Gamma_{\text{max}}$ is the maximum of all the rates of the ripples in the system at time $t$. Denote the mass of the selected ripple by $m$. If $x < \Gamma(m)/\Gamma_{\text{max}}$, where $x$ is an uniformly distributed random number in the interval $[0, 1]$, the ripple gets a unit mass from its nearest neighbor. Otherwise a new ripple is selected and the process is repeated. For symmetric dynamics the neighbor is selected randomly whereas in the asymmetric case it is always the right one.

**B. Relation to other models**

The model defined above is inspired by the worm model originally introduced to describe the coarsening of wind ripples [8]. Here it is generalized in two respects. First, the mass transfer rate in the worm model is inversely proportional to the ripple mass whereas in the generalized model it is given by $\Gamma(m) \sim m^\gamma$. Second, we consider also the symmetric mass transfer between neighbors. In the case of asymmetric dynamics and for $\gamma = -1$ our model reduces to the worm model.

Apart from the extinction step, the sand ripple model is similar to a zero range process [10, 11, 12]. Both models are defined in terms of conserved, integer mass variables $m_i$ which interact through the (symmetric or asymmetric) exchange of unit masses between nearest neighbor sites of a lattice. The key difference is that in a zero range process the mass transfer rate is a function of the mass at the site of departure, while in the sand ripple model it depends on the mass at the target site. This reverses the sign of the right hand sides of (1) and (2), and hence the stability properties of the model: In a zero range process the homogeneous state is stable if $\Gamma'(\bar{m}) > 0$ and unstable if $\Gamma'(\bar{m}) < 0$. The coarsening behavior in zero range processes with nonmonotonic robber function is relevant to clustering in granular gases [6].

The occurrence of irreversible extinction events in our model is reminiscent of certain urn models that have been proposed in the context of glassy dynamics [13]. For example, consider the backgammon model [14] which is defined by $M$ particles distributed among $N$ boxes with $m_i$ particles in the $i$th box. The Hamiltonian is $H = -\sum_i \delta_{m_i,0}$ so that the energy corresponds to minus the number of empty boxes. The $N$-fold degenerate ground state therefore consists of a condensate, where all the particles belong to one box. Associating the masses of ripples with the particle numbers and lattice sites with boxes, the ripple evolution becomes similar to the backgammon model at zero temperature, where the empty boxes are not refilled once they have become empty (ripple extinction).

In contrast to the ripple model, the urn models have no spatial structure, i.e., mass transfer is possible between any pair of boxes. In the standard dynamical scheme, originally due to Ehrenfest, in each time step one of the balls is chosen at random and a move to another box is attempted [13]. The probability for a box to be chosen is then proportional to its occupation number. In our setting this corresponds to a mass transfer rate $\Gamma(m_i) \sim m_i$, where $i$ is the site of departure; in this respect the urn models are related to zero range processes. Since $\Gamma' > 0$, the homogeneous state is linearly stable and coarsening (i.e., evolution towards the ground state) is very slow.

The sand ripple model can also be mapped to an exclusion process [10, 12, 14]. The mapping can be done in two ways which differ in how the disappearance of ripples is taken into account. The mappings proceed along the lines of [12] and the first one is schematically presented in Fig. 2. One constructs a new lattice with $L(t) = M + N(t)$ sites. The mass variables $m_i$ of the ripples turn to $m_i$ consecutive holes separated by particles on the new lattice. More precisely, there exist particles on sites $i + \sum_{k=1}^i m_k$ ($i = 1, \ldots, N(t)$) while the rest are empty. Moving one mass unit from one ripple to its neighbor corresponds to a hop of a particle in the exclusion process. Naturally the exclusion process is either symmetric or asymmetric as the original dynamics. For the exclusion process the loss of a ripple becomes a coalescence of particles at contact, which changes the length $L(t)$ of the system.

As the masses map to holes, the hopping rates of parti-
FIG. 3: Mapping between the worm model, the asymmetric exclusion process (ASEP), and the cluster–cluster aggregation (CCA).
$m_{i+1}$ and the last term describes the rate at which the site $i$ gains mass from its neighbor. We emphasize that, provided a solution to (4) can be found, this proves that the product measure (3) is an exact stationary solution of the master equation; on the basis of general arguments, this solution is then also expected to be unique.

Proceeding similarly for the symmetric dynamics gives (transitions $\{\ldots, m_i-1, m_i, m_{i+1}, \ldots\} \rightarrow \{\ldots, m_i-1, m_i+1, m_{i+1}, \ldots\}$ and $\{\ldots, m_i+1, m_{i+1}, \ldots\} \rightarrow \{\ldots, m_{i-1}, m_i+1, m_{i+1}, \ldots\}$)

$$p(m_{i-1})p(m_i)p(m_{i+1})\Gamma(m_i) = p(m_{i-1})p(m_i)p(m_{i+1})\Gamma(m_{i-1} - 1). \quad (5)$$

Since $p(m_{i+1})$ cancels out we end up with Eq. (4). Therefore the steady state distribution is independent of the asymmetry of the dynamics.

Equation (4) can be recast as

$$\alpha^{-1} := \frac{p(m_i)p(m_i+1)}{p(m_i+1)} = \frac{p(m_{i+1} - 1)p(m_{i+1} - 1)}{p(m_{i+1})}, \quad (6)$$

where $\alpha$ must be a constant. Denoting $p(0) = p_0$ and recursively iterating equation (3), we obtain

$$p(m) = p_0 \alpha^m \prod_{i=1}^{m-1} \Gamma(i) = p_0 \alpha^m [(m-1)!]^\gamma, \quad (7)$$

where the product for $m = 1$ is defined to give unity and the last form follows from the definition $\Gamma(m) = m^\gamma$.

The unknown constants $p_0$ and $\alpha$ can be determined by the normalization $\sum_{m=0}^{\infty} p(m) = 1$ and the expectation value $\langle m \rangle := \sum_{m=0}^{\infty} mp(m)$. Explicit results for $\gamma = -1$ and $-2$ can be found in Appendix A for $\gamma = -1$, [6] is a (shifted) Poisson distribution. In general, the distribution for $\langle m \rangle \gg 1$ can be written as

$$p(m) = C_2(\gamma)e^{\gamma(m)}\langle m \rangle^{-\gamma - (1-\gamma)/2}[(m-1)!]^\gamma, \quad (8)$$

where the explicit form of $C_2(\gamma)$ is not important for our purposes. Using the form given in Eq. (6), it is easy to show that the width $\sigma := \sqrt{\langle m^2 \rangle - \langle m \rangle^2}$ of the distribution behaves as $\sigma \sim \sqrt{\langle m \rangle}$ independent of $\gamma$.

The calculated distributions are compared to numerics in Figs. 4 and 5. The average ripple mass is not a constant as the simulations include also ripple extinction. The excellent agreement at long times shows that indeed these become so rare, that between subsequent extinctions the system has time to equilibrate to the steady state. Note that all initial distributions converge to the universal distribution $p(m; t)$ given by Eq. (6), where the time-dependence enters only through the mean ripple mass $\langle m \rangle(t)$.

**B. Coarsening law**

Next we proceed to calculate the mean ripple size $\langle m \rangle(t)$ using an approach similar to the analysis of the backgammon model [11]. We assume that, at long times, the probability for a given ripple to vanish is equal to the probability $p(0)$ obtained by extrapolating the steady state probability distribution (3) to $m = 0$. The number $N$ of ripples then decays according to $dN/dt \approx -p(0)N$. 

![FIG. 4: The ripple size distributions obtained from simulations for $\gamma = -1$ at $t = 4$ (×), 256 (○), 16384 (◇), and 2097152 (□) together with the analytical result (solid lines) [Eqs. (8) and (3)]. The initial distribution at $t = 0$ is a random one and simulations are averaged over 2000 runs for a system of size $M = 50000$. The dashed line shows the asymptotic solution given by Eq. (3) for $t = 2097152$.](image)

![FIG. 5: The ripples size distributions obtained from simulations for $\gamma = -0.5$ at $t = 4$ (×), 128 (○), 4096 (◇), and 131072 (□) together with the analytical result (solid lines) [Eq. (3)]. The initial distribution at $t = 0$ is a random one and simulations are averaged over 500 runs for a system of size $M = 50000$. The dashed line shows the asymptotic solution given by Eq. (3) for $t = 131072$.](image)
Since \( \langle m \rangle(t) = M/N \) we obtain
\[
\frac{d\langle m \rangle(t)}{dt} \approx p(0)\langle m \rangle(t) \sim e^{\gamma \langle m \rangle} \langle m \rangle^{-(1-\gamma)/2},
\] (9)
which to leading order in \( t \) gives
\[
\langle m \rangle(t) \approx -\gamma^{-1} \ln(t).
\] (10)
Simulations with different initial conditions are in accord with Eq. (10) (Fig. 6).

C. Decay of correlations

The product measure for the ripple size distribution implies that there are no correlations between neighboring ripples. This is true only asymptotically. To study the approach to the product measure distribution we consider the normalized nearest neighbor time correlation function
\[
g(t) := \frac{\langle m_i m_{i+1} \rangle - \langle m \rangle^2}{\langle m \rangle^2}.
\] (11)
As is clear from Fig. 7, the early time behavior is sensitive to the details of the initial distribution. In this regime it is possible to have positive correlation between neighboring ripples but at long times there will always be anticorrelations, i.e., \( g(t) < 0 \). The numerically observed correlations seem to be independent of the initial conditions and vanish in a universal manner as
\[
g(t) \sim -t^{-1/2}
\] (12)
for both symmetric and asymmetric dynamics.

At first sight one may be tempted to relate the decay of correlations to the extinction events, which perturb the product measure. However, as was shown in Sec. III B, the probability of extinction events decays as \( p(0) \sim e^{\gamma \langle m \rangle(t)} \sim t^{-1} \), which is much faster than the numerically observed decay law (12). This implies that the power law (12) is associated with the dynamics between extinction events, which can be described using standard hydrodynamic fluctuation theory for a one-dimensional system with a single conserved density.

Let \( \phi(x,t) \) denote the coarse grained mass fluctuations in the (quasi-) steady state of mean mass \( \langle m \rangle \). The long wavelength behavior of \( \phi \) is governed by a Langevin equation of the generic form (14)
\[
\frac{\partial \phi}{\partial t} = \nu \frac{\partial^2 \phi}{\partial x^2} - \mu \frac{\partial \phi}{\partial x} - \frac{\partial \eta}{\partial x},
\] (13)
where \( \eta(x,t) \) is Gaussian white noise with covariance \( \langle \eta(x,t)\eta(x',t') \rangle = D \delta(x-x')\delta(t-t') \). For \( \mu \neq 0 \), Eq. (13) is the noisy Burgers equation (20), which has been widely studied in the context of driven diffusive systems (19) and interface growth (21-23).

The coefficients \( \nu, \mu \), and \( D \) appearing in the long wavelength description can be related to the microscopic dynamics of the sand ripple model as follows. The nonlinear term on the right hand side of Eq. (14) is generated by the asymmetry, and its coefficient is given by \( \mu = C^j \langle m \rangle \), where \( j \) is the steady state mass current. Since in our case \( j = \Gamma \), we conclude that \( \mu \sim \langle m \rangle^{\gamma-2} \).

In the symmetric case \( \mu = 0 \) and the diffusion coefficient
\( \nu \) is proportional to \( \Gamma' \sim \langle m \rangle^{-1} \) (this can be seen by expanding Eq. (1) around the homogeneous state). Finally, owing to a fluctuation-dissipation theorem \( 22 \), the equal time correlations of \( 13 \) are Gaussian with covariance \( \langle \phi(x)\phi(x') \rangle \sim (D/\nu)\delta(x-x') \) independent of \( \mu \). As we have shown above in Sec. IIIA in the ripple model the variance of the mass fluctuations is always of order \( \langle m \rangle \), hence \( D/\nu \sim \langle m \rangle \).

We want to use equation (13) to describe the approach to the steady state, starting from some initial condition (e.g., the monodisperse state \( \phi = 0 \)) specified at \( t = 0 \). The analysis of Eq. (13) shows that at long times, and for \( x \neq x' \), the pair correlation function takes the scaling form \( 22 22 \)

\[
\langle \phi(x,t)\phi(x',t) \rangle = \frac{D}{\nu} \frac{1}{\xi(t)} G(\xi(t)^{-1}|x-x'|). \tag{14}
\]

Here \( G \) is a scaling function, and \( \xi(t) \) denotes the dynamic correlation length. The prefactor of the scaling function on the right hand side of Eq. (14) is fixed by the requirements that (i) the steady state density fluctuations are proportional to \( D/\nu \), and (ii) the integral over the pair correlation function is constant due to mass conservation. The correlation length grows diffusively as \( \xi(t) \sim (\nu t)^{1/2} \) for \( \mu = 0 \) and superdiffusively as \( \xi(t) \sim [(D/\nu)^{1/2} \mu t]^{2/3} \) for \( \mu \neq 0 \).

Keeping \( |x-x'| \) fixed and taking \( t \to \infty \), we see that the pair correlations (13) decay as \( (D/\nu)G(0)\xi(t)^{-1} \). Expressing \( \nu \) and \( D/\nu \) in terms of the mean ripple mass, we conclude that in the symmetric case \( (\mu = 0) \) the normalized correlation function (12) should decay as

\[
g(t) \sim \frac{\langle m \rangle^{-1/(1+\gamma)/2}}{t^{1/2}} \sim \frac{(\ln t)^{-1/(1+\gamma)/2}}{t^{1/2}}. \tag{15}
\]

For \( \gamma = -1 \) the logarithmic factor disappears and (13) becomes a pure power law with exponent \(-1/2\), in accordance with the simulation results shown in Fig. 3. Moreover, the explicit calculation for the diffusive case shows that the scaling function \( G \) in Eq. (14) is negative, hence \( g(t) < 0 \) as observed numerically.

In the asymmetric case the fluctuation theory predicts an asymptotic decay as \( g(t) \sim 1/\xi(t) \sim t^{-2/3} \), with logarithmic corrections due to the growth of \( \langle m \rangle(t) \). Then why do we find \( g(t) \sim t^{-1/2} \) also for asymmetric dynamics? To answer this question, we recall that the asymptotic, superdiffusive behavior predicted by the noisy Burgers equation sets in only beyond a crossover time scale \( t_x \), which increases rapidly with decreasing strength \( \mu \) of the nonlinear term \( 22 \). The crossover time is of the order of \( t_x \sim \nu^3/(D/\nu)^4 \). Inserting the estimates for \( \mu, \nu, \) and \( D/\nu \) derived above, we see that for the ripple model

\[
t_x \sim \langle m \rangle^{3-\gamma} \sim (\ln t)^{3-\gamma}. \tag{16}
\]

For the case \( \gamma = -1 \) considered in Fig. 3, this implies that superdiffusive behavior can be expected only for times such that \( t/(\ln t)^4 \gg 1 \). The left hand side of this inequality becomes equal to unity for \( t \approx 5500 \) and reaches the value 10 only for \( t \approx 235000 \). Thus the asymptotic regime has not been reached in our simulations. The slight deviation of the simulation data from the \( t^{-1/2} \) behavior seen after \( t = 10^5 \) may indicate the beginning of the crossover.

### IV. UNSTABLE COARSENING (\( \gamma > 0 \))

For \( \gamma > 0 \) the homogeneous state is linearly unstable because the largest ripples are those with the highest growth rate. Ripple extinction is then no longer a rare event, and the product measure solution derived in Sec. IIIA becomes invalid. On the other hand, it is plausible (and will be confirmed by simulations, see below) that the linear instability supersedes the noise in the time evolution, so that the deterministic equations (1) and (2) and the stochastic ripple model show the same behavior.

In what follows, we first develop a mean-field theory for the deterministic model in the simplest case of a linear rubber function \( (\gamma = 1) \). Simulations show that the mean field theory is not quantitatively correct, presumably due to the neglect of spatial fluctuations. In the nonlinear regime \( 0 < \gamma < 1 \) we use scaling analysis to derive the coarsening law.

#### A. Mean-field analysis for \( \gamma = 1 \)

We start our analysis from the deterministic equations (1) and (2). For \( \gamma = 1 \) these become linear but the system is still non-trivial due to the ripple extinction. As the system is deterministic, the only randomness lies in the initial condition. We denote the initial ripple size distribution by \( P_0(\lambda_0) \) and its average by \( \langle \lambda_0 \rangle \).

The mean field approximation consists of replacing the ripples surrounding an arbitrary ripple of size \( \lambda \) by ripples of the average size \( (\lambda) \), such that the evolution equation becomes

\[
\frac{d\lambda}{dt} = \frac{\Gamma(\lambda) - \Gamma(\langle \lambda \rangle)}{\lambda - \langle \lambda \rangle}. \tag{17}
\]

On this level there is no difference between symmetric and asymmetric mass transfer. The solution of Eq. (17) reads \( \lambda(\lambda_0,t) = e^{t[\lambda_0 - F(t)]} \), where the function

\[
F(t) := \int_0^t d\tau e^{-\tau} \langle \lambda \rangle(\tau) \tag{18}
\]

has to be calculated self-consistently. Note that at this point we do not explicitly restrict \( \lambda(t) \) to be nonnegative (this constraint will enter later). Once \( F(t) \) is known, the ripple size distribution at time \( t \) can be obtained by inverting the solution for \( \lambda(\lambda_0) \) and inserting this into the initial distribution, with the result

\[
p(\lambda;t) = e^{-t}P_0(e^{-t}\lambda + F(t)). \tag{19}
\]
Thus in the mean-field approximation the ripple size distribution preserves its initial shape but gets scaled and shifted.

It is possible to derive a differential equation for the unknown function $F(t)$. The fraction $\rho(t)$ of surviving ripples is equal to the probability that $\lambda(t) > 0$,

$$\rho(t) = \int_0^\infty d\lambda \, P(\lambda; t) = \int_{F(t)}^\infty dx P_0(x) =: P_0^*(F(t)), \quad (20)$$

where the last equation defines the cumulative distribution $P_0^*$. The average ripple size is given by $\langle \lambda \rangle(t) = \bar{\lambda}_0/\rho(t)$. Inserting this into the definition of $F(t)$ and differentiating once gives

$$\frac{dF(t)}{dt} = \frac{e^{-t}\bar{\lambda}_0}{P_0^*(F(t))}, \quad (21)$$

Hence the problem reduces to solving the differential equation (21) for a given initial distribution $P_0(\lambda)$.

For example, for an exponential initial distribution $P_0(\lambda_0) = \lambda_0^{-1} e^{-\lambda_0/\lambda_0}$, we find $F(t) = \lambda_0 t$ and $\langle \lambda \rangle(t) = \lambda_0 e^{t}$, whereas for a flat distribution

$$P_0(\lambda_0) = \begin{cases} (2\bar{\lambda}_0)^{-1} & \lambda_0 \leq 2\bar{\lambda}_0 \\ 0 & \text{otherwise} \end{cases} \quad (22)$$

the solution is given by $F(t) = 2\bar{\lambda}_0(1 - e^{-t/2})$ and $\langle \lambda \rangle(t) = \lambda_0 e^{t/2}$. As the rate of exponential growth is different in these two cases, we conclude that the coarsening behavior of the mean field model (15) is nonuniversal.

In general, the exponential growth rate of the mean ripple size is governed by the extremal statistics of the initial distribution $P_0$. If the initial ripple sizes are bounded by a maximal size $\lambda_{\text{max}}$, and $P_0(\lambda_0) \sim (\lambda_{\text{max}} - \lambda_0)^g$ for $\lambda_0 \to \lambda_{\text{max}}$, then the analysis of Eq. (21) shows that $t^{-1} \ln(\langle \lambda \rangle(t)) \to (a + 1)/(a + 2)$, while for flat initial distributions with a power law tail, $P_0(\lambda_0) \sim \lambda_0^{-(b+1)}$, we find $t^{-1} \ln(\langle \lambda \rangle(t)) \to b/(b - 1)$.

To compare the predictions of the mean-field theory to simulations we prefer to show the complement of the cumulative distribution

$$I(\lambda; t) := \int_{\lambda}^\infty dx \, p(x; t) =: f \left( \frac{\lambda}{\langle \lambda \rangle(t)} \right), \quad (23)$$

where the last equation defines the scaling function $f(x)$. A similar definition applies to $p(m; t)$ with the integral replaced by a sum. In the case of an exponential distribution $p(\lambda; t)$ also the function $f(x)$ is exponential whereas for a flat $p(\lambda; t)$ it is linear.

We solved the deterministic equations (1) and (17) using the fourth-order Runge-Kutta method (24). As a check of the algorithm, we reproduced the solution (19) of the mean-field equations. For the full noisless system (4) the exponential initial distribution remains unchanged [Fig. 8 a); dashed lines] but also a flat initial distribution presumably approaches the exponential one [Fig. 8 b); dashed lines]. This is in conflict with the mean-field prediction. In both cases the average ripple size grows as $\langle m \rangle(t) \sim e^t$.

Similarly, in the discrete, noisy ripple model the random initial distribution quickly converges towards an exponential scaling function [Fig. 8 a); solid lines]. The monodisperse initial condition spreads out and approaches the same form [Fig. 8 b); solid lines]. Again, the mean ripple size grows as $\langle m \rangle(t) \sim e^t$ for both initial distributions.

Since the deterministic model behaves in a similar manner as the noisy one, we conclude that, in contrast to the case $\gamma < 0$, the noise is irrelevant. The discrepancy between the mean-field theory and the full deterministic system suggests that the spatial fluctuations are important, as is often the case for low dimensional systems. In particular, the numerical results indicate that, in contrast to the mean field prediction, the behavior of the full system is universal with respect to the initial ripple size distribution.
B. Coarsening law for $0 < \gamma < 1$

As the mean-field equation is not readily solvable for $\gamma \neq 1$ and probably would not describe the problem correctly anyway, here we present a simple scaling argument for the growth of the mean ripple size in the regime $0 < \gamma < 1$. We start from the observation that in the linearly unstable case ($\Gamma'(\lambda) > 0$) predominantly every second ripple grows and every second one shrinks. Therefore we may consider a simplified system consisting of two ripples of initial sizes $\lambda_1^0 > \lambda_2^0$. We calculate the time $t^*$ at which the average size has doubled. It is given by the conditions $\lambda_1(t^*) = \lambda_1^0 + \lambda_2^0$ and $\lambda_2(t^*) = 0$. Since the mass is conserved we have $\bar{\lambda} := \lambda_1(t) + \lambda_2(t) = \text{const.}$.

Applying Eq. (11) gives

\[
\begin{cases}
\dot{\lambda}_1 &= \lambda_1^2 - \lambda_2^2, \\
\dot{\lambda}_2 &= \lambda_2^2 - \lambda_1^2,
\end{cases}
\]

(24)

where the dot denotes derivative with respect to time. The solution is implicitly given by $\lambda_2(t) = \bar{\lambda} - \lambda_1(t)$ and

\[
t = \int_{\lambda_1^0}^{\lambda_1(t)} \frac{dx}{x^{\gamma} - (\bar{\lambda} - x)^{\gamma}},
\]

(25)

which together with the definition of $t^*$ implies the homogeneity relation

\[
t^* (a \lambda_1^0, a \bar{\lambda}) = a^{1-\gamma} t^* (\lambda_1^0, \bar{\lambda}).
\]

(26)

Assuming that the evolving ripple size distribution is governed by a single size scale, it follows that the doubling time depends on the mean ripple size as $t^* \sim \langle \lambda \rangle^{1-\gamma}$. The inverse of the doubling time is the growth rate of $\langle \lambda \rangle$. Hence we may write

\[
\frac{d\langle \lambda \rangle(t)}{dt} \sim \frac{1}{t^*} \langle \lambda \rangle(t)
\]

(27)

which yields $\langle \lambda \rangle(t) \sim t^z$ with $z = 1/(1-\gamma)$. This is confirmed by simulations, which give $z = 1.32 \pm 0.02$ and $1.98 \pm 0.03$ for $\gamma = 0.25$ and 0.50, respectively. We also numerically checked the universal scaling behavior of the ripple size distribution for $0 < \gamma < 1$, but in this region the scaling function is more complicated than a simple exponential.

V. CONCLUSIONS

In this paper we have studied a one-dimensional model for sand ripple evolution, where mass is transferred between neighboring sites with algebraic rates and sites containing no mass are removed from the system (ripple extinction). As the rates depend only on the site to which the mass is transferred, the system is similar to a zero range process. Thus the steady state in the absence of ripple extinction is characterized by a product measure. Asymptotically this continues to hold for algebraically decaying mass transfer rates ($\gamma < 0$) since the extinctions are exponentially rare at late times. As a consequence the average ripple size grows to leading order logarithmically slowy with the prefactor $-1/\gamma$.

For $\gamma < 0$ the approach to the steady state product measure is algebraic. The correlations between masses of neighboring ripples decay universally, i.e., independent of the initial distribution, as $t^{-1/2}$ and $t^{-2/3}$ for symmetric and asymmetric mass transfer, respectively. In the asymmetric case the asymptotic regime is preceded by a long crossover where $t^{-1/2}$-decay is observed.

For algebraically growing robber functions ($\gamma > 0$) the coarsening is driven by the linear instability of the homogeneous state. Ripple extinctions become frequent, and the product measure is no longer relevant. The average ripple size grows algebraically as $t^{1/(1-\gamma)}$ for $0 < \gamma < 1$. The behavior at $\gamma = 0$ is discontinuous since $\langle m(t) \rangle \sim t^{1/2}$ for $\gamma = 0$, which follows from the mapping to coalescing random walkers. For $\gamma = 1$ ($m(t) \sim t^\gamma$) and the scaling function of the ripple size distribution appears to be a simple exponential. The dynamical noise, which is necessary to have coarsening for $\gamma \leq 0$, is irrelevant for $\gamma > 0$. The mean-field theory developed for $\gamma = 1$ reproduces the exponential growth of the mean ripple size, but it is insufficient to describe the universality of the growth law and the ripple size distribution which is observed numerically.

It is interesting to compare the results to the behavior in one-dimensional cluster-cluster aggregation. Recall that the model treated here can be mapped to cluster-cluster aggregation with hopping rates of clusters depending algebraically on the distance between them (Sec. III B). When the hopping rates depend as $\Gamma(m) \sim m^{\gamma}$ on the masses of clusters, the growth of the average cluster size is algebraic with $\langle m(t) \rangle \sim t^{1/(2-\gamma)}$ for $0 < \gamma < 1$ [6]. Thus the behavior for nonnegative values of $\gamma$ is rather similar in the two models, but for $\gamma < 0$ one finds a drastic difference due to the repulsive interaction between clusters in the ripple model.

We conclude by adducing some open problems for future studies. One of the most interesting issues is to understand the coarsening and the final ripple size selection in the case of a nonmonotonic robber function. This has direct applications in the coarsening of vortex ripples, where the robber function has recently been measured [4]. Initially these systems are in the unstable regime, where the transfer function is monotonically increasing. As we have seen in the present article, even this is a harder problem than the case where the dominant contribution to coarsening comes from the dynamical fluctuations. For nonmonotonic robber functions one needs an understanding of both coarsening mechanisms. Therefore the starting point into this direction would be to better understand the $\gamma > 0$ case.

*APPENDIX A: CALCULATION OF MASS DISTRIBUTIONS FOR $\gamma = -1$ AND $-2$*

Here we calculate the explicit form of the mass distribution

$$p(m) = \frac{1}{\Gamma(m)} \prod_{i=1}^{m-1} \Gamma(i) = \frac{\alpha^m[m(m-1)!]^\gamma}{m!},$$  \hspace{1cm} (A1)

for $\Gamma(m) = m^\gamma$ in the cases $\gamma = -1$ and $-2$. For $m = 1$ the product in Eq. (A1) for $m = 1$ is defined to be unity, and we set $(-1)! = 1$. The normalization condition $\sum_{m=0}^\infty p(m) = 1$ gives

$$p(m) = \begin{cases} (1 + \alpha e^\alpha)^{-1} \alpha^m/(m-1)! & \text{for } \gamma = -1 \\ \Gamma^{-1}(1 + \alpha e^\alpha) \alpha^m/(m-1)! & \text{for } \gamma = -2, \end{cases}$$  \hspace{1cm} (A2)

where $I_n(x)$ is the modified Bessel function of the first kind. The parameter $\alpha$ is related to the expectation value $\langle m \rangle = \sum_{m=0}^\infty mp(m)$ by

$$\langle m \rangle = \begin{cases} \alpha(\alpha + 1)e^\alpha / (1 + \alpha e^\alpha) & \text{for } \gamma = -1 \\ 1 + \sqrt{\alpha} I_1(2\sqrt{\alpha}) / I_0(2\sqrt{\alpha}) & \text{for } \gamma = -2, \end{cases}$$  \hspace{1cm} (A3)

Using the expansions $I_n(x) = e^x/\sqrt{\pi x} + O(1/x)$ for $x \to \infty$, these formulae simplify to $\langle m \rangle \approx \alpha$ and $\langle m \rangle \approx \sqrt{\alpha}$, for $\gamma = -1$ and $-2$, respectively. Hence for $\langle m \rangle \to \infty$ the distributions become

$$p(m) \approx \begin{cases} e^{-(m)}(m)^{m-1}/(m-1)! & \text{for } \gamma = -1 \\ 2\sqrt{\pi e^{-2m}}(m)^{2m-3/2}/[(m-1)!]^2 & \text{for } \gamma = -2, \end{cases}$$  \hspace{1cm} (A4)

which are of the general form indicated in Eq. (8).
