Abstract This study reports the first detailed geochemical characterization of Kolumbo submarine volcano in order to investigate the role of source heterogeneity in controlling geochemical variability within the Santorini volcanic field in the central Aegean arc. Kolumbo, situated 15 km to the northeast of Santorini, last erupted in 1650 AD and is thus closely associated with the Santorini volcanic system in space and time. Samples taken by remotely-operated vehicle that were analyzed for major element, trace element and Sr-Nd-Hf-Pb isotope composition include the 1650 AD and underlying K2 rhyolitic, enclave-bearing pumices that are nearly identical in composition (73 wt.% SiO2, 4.2 wt.% K2O). Lava bodies exposed in the crater and enclaves are basaltic andesites (52–60 wt.% SiO2). Biotite and amphibole are common phenocryst phases, in contrast with the typically anhydrous mineral assemblages of Santorini. The strong geochemical signature of amphibole fractionation and the assimilation of lower crustal basement in the petrogenesis of the Kolumbo magmas indicates that Kolumbo and Santorini underwent different crustal differentiation histories and that their crustal magmatic systems are unrelated. Moreover, the Kolumbo samples are derived from a distinct, more enriched mantle source that is characterized by high Nb/Yb (>3) and low 206Pb/204Pb (<18.82) that has not been recognized in the Santorini volcanic products. The strong dissimilarity in both petrogenesis and inferred mantle sources between Kolumbo and Santorini suggests that pronounced source variations can be manifested in arc magmas that are closely associated in space and time within a single volcanic field.

1. Introduction

Kolumbo is a submarine volcano that is situated ca. 15 km to the northeast of the center of Santorini caldera in the central part of the Aegean arc, Greece [Sigurdsson et al., 2006; Nomikou et al., 2012, 2013b]. Between September and November 1650 AD, Kolumbo erupted violently, resulting in the death of livestock and over 60 inhabitants on Santorini due to the release of noxious gasses [Fouqué, 1879; Dominey-Howes et al., 2000; Cantner et al., 2014; Nomikou et al., 2014a]. Ash fallout reached as far as mainland Turkey and a pumice edifice rose above sea level, but was quickly eroded to below the wave base. Today, the products of the 1650 AD eruption in the surviving submarine crater comprise a ca. 250 m thick sequence of white, crystal poor pumices of rhyolitic composition [Cantner et al., 2014] that overlay an older cone-shaped structure [Nomikou et al., 2012]. A recent multichannel reflection seismic study identified five distinct volcanic units, thus establishing that Kolumbo has a polygenetic, composite structure [Hübischer et al., 2015] (Figure 1). Two of these units, the K2 pumice and 1650 AD pumice (unit KS in Hübischer et al. [2015]), and several poorly defined intrusive bodies are exposed in the crater walls. The cone-shaped 3D geometry of the Kolumbo deposits indicates that their source is the Kolumbo vent and that they do not represent distal deposits of the major Plinian eruptions of Santorini. Whether the magmatic systems of Kolumbo and Santorini are related at depth, however, is uncertain. A recent tomographical study has suggested that the shallow (5–7 km depth) magma chamber underneath Kolumbo has a possible lateral extension toward the plumbing system of Santorini [Dimitriadis et al., 2010]. A possible link between the two magmatic systems implies that the Kolumbo volcanic products could be genetically related to the recent Nea Kamени dacites on Santorini (197 BC to present [Druitt et al., 1999]). Alternatively, the silicic 1650 AD pumices could represent evolved residual
magma from the caldera-forming 3.6 ka Minoan eruption of Santorini, or the two volcanoes could be unrelated. The aim of this study is to establish if magmas of Kolumbo and Santorini follow the same crustal differentiation trends and therefore if their volcanic plumbing systems are related. The latter is of particular interest for the assessment of volcanic risks in the Santorini volcanic field. We have undertaken a comprehensive petrological and geochemical study of Kolumbo volcanic products that were sampled from the crater walls with the use of a remotely-operated vehicle (ROV) [Carey et al., 2011; Bell et al., 2012]. The first trace element and radiogenic isotope data are reported for Kolumbo submarine volcano, which include high-precision double spike Pb isotope analyses. These new data contribute toward the understanding of the dynamics of magma generation and differentiation in the central section of the Aegean arc.

2. Geological Setting

Kolumbo and 19 smaller (<2 km²) submarine volcanic cones form a chain that constitutes the northernmost part of the Santorini volcanic field (Figure 1) [Nomikou et al., 2012, 2013a]. The Santorini volcanic field is one of the main volcanic centers of the Aegean arc, which has formed as a result of northward subduction of the African plate underneath Eurasia. Slab roll-back has induced active extension in the Aegean region and southward migration of the volcanic front, demonstrated by the onset of activity in the present Aegean arc at ca. 4 Ma [e.g., Pe-Piper and Piper, 2005]. The extensional tectonic regime in the southern Aegean strongly controls the locus of volcanism in the Santorini volcanic field. As a result, the Christiana Islands, Santorini, and the Kolumbo volcanic chain have developed along the Christiana-Santorini-Kolumbo (CSK) tectonic line.
KOLUMBO SUBMARINE VOLCANO 3256

The present-day Kolumbo crater is roughly oval shaped with a diameter of ca. 1700 m and a depth of ca. 200 m below sea level (b.s.l. to the crater floor with the highest point of the crater rim at 18 m b.s.l. (Figure 1) [Nomikou et al., 2012; Parks et al., 2012; Feuillet, 2013]. At least five distinct volcanic units have been identified in Kolumbo on the basis of seismic imaging [Hübscher et al., 2015], as well as several poorly defined shallow intrusive bodies that have been interpreted as a set of NE-SW dykes [Killas et al., 2013]. The youngest volcanic products of Kolumbo comprise an over 250 m thick package of stratified pumices that was deposited during the 1650 AD eruption and is described in detail by Cantrner et al. [2014]. At present, there are no absolute geochronological constraints on the age of the underlying volcanic units, although Hübscher et al. [2015] correlate the K2 pumice with the 145 ka Middle Tuffs of Santorini [Keller et al., 2000] on the basis of the thickness of the intercalated sediments. This presumed age implies that volcanic activity of Kolumbo was synchronous with the second explosive cycle on Santorini [Druitt et al., 1999]. Of particular interest for investigating a relationship between Santorini and the 1650 AD eruption of Kolumbo are the most recent volcanic products of Santorini, the Minoan Tuff and the Kameni dacites. The rhyodacitic Minoan Tuff was emplaced during the last major, caldera-forming eruption of Santorini that marked the end of the second explosive cycle at 1627–1620 BC [Friedrich et al., 2006] and is described in detail in Cottrell et al. [1999] and Druitt [2014]. After the Minoan caldera collapse, subaerial activity resumed in 197 BC with the extrusion of dacitic lava flows on the island of Palaea Kameni in the center of Santorini caldera. On adjacent Nea Kameni, subaerial dacitic lavas have been emplaced intermittently from 1570 to 1950 AD [Druitt et al., 1999; Martin et al., 2006; Nomikou et al., 2014b] and hence these Kameni dacites have a close temporal association with the 1650 AD eruption of Kolumbo.

3. Analytical Techniques

Samples of the Kolumbo volcanic deposits were acquired with an ROV during 2010 (NA007) and 2011 (NA014) cruises of the Exploration Vessel Nautilus (see Figure 1 for sampling locations). Due to the limitations of the ROV robot arm, sampling was restricted to loose clast <10 cm in size, but it was possible to obtain samples from the pumice and lava bodies. A total of 15 Kolumbo samples were initially analyzed for major and minor element composition by X-ray fluorescence spectroscopy (XRF) at the University of Rhode Island. Five of these samples and six new samples were subsequently analyzed for trace element and Sr-Nd-Hf-Pb isotope composition at the Vrije Universiteit Amsterdam. For comparison, five samples of the Nea Kameni dacites and Minoan Tuff of Santorini have been included in the sample set (see supporting information for sample details). Pumice and lava samples were cut in smaller pieces with a diamond saw, carefully removing any weathered parts, and subsequently cleaned thoroughly in demineralized water in an ultrasonic bath. After drying, pumice samples were lightly crushed in an agate pestle and mortar after which fragments of mafic enclaves were carefully removed. For one K2 pumice sample, a sufficient amount of enclave fragments (ca. 10 g) was separated to allow geochemical characterization. Lava samples were reduced in size using a hardened-steel jawcrusher. The lightly crushed pumice and lava fragments were reduced to a powder using an agate planetary ball mill.

The major element composition of the new samples was determined by XRF on fused glass beads. Sample powders were ignited at 1000 °C for 2 h to determine loss on ignition before being mixed with Li2B4O7/LiBO2 mixture (1:4 dilution), fused to a bead at 1150 °C and measured on a Panalytical AxiosMax XRF instrument at the University of Rhode Island. All XRF results are reported on a volatile-free basis normalized to 100 wt.% with Fe expressed as total ferrous iron (FeO*). Replicate analyses of samples previously analyzed at the University of Rhode Island indicate that results from the two laboratories are within analytical uncertainty (<3% relative standard deviation for major elements). Aliquots of selected samples were subsequently digested in PTFE bombs in a HF/HNO3 mixture after which trace element concentrations were measured...
by ICPMS and Sr-Nd and Hf isotopes by TIMS and MC-ICPMS respectively, following the procedures outlined in Klaver et al. [2015]. Over the course of this study, standard reference material (SRM) 987 yielded $^{87}\text{Sr}/^{86}\text{Sr} = 0.710251 \pm 0.000030$ (2 SD, n = 6), in-house Nd reference material CIGO yielded $^{143}\text{Nd}/^{144}\text{Nd} = 0.511331 \pm 0.000008$ (2 SD, n = 6; equivalent to a value of 0.511841 for La Jolla [Griselin et al., 2001]) and the JMC-475 Hf standard reagent gave $^{176}\text{Hf}/^{177}\text{Hf} = 0.282169 \pm 0.000009$ (2 SD, n = 19). Lead isotopes were measured by TIMS using a $^{207}\text{Pb}/^{204}\text{Pb}$ double spike to correct for instrumental mass fractionation [Klaver et al., 2016b], giving a reproducibility for SRM 981 of $^{206}\text{Pb}/^{204}\text{Pb} = 16.9412 \pm 0.0004$, $^{207}\text{Pb}/^{204}\text{Pb} = 15.4987 \pm 0.0003$ and $^{208}\text{Pb}/^{204}\text{Pb} = 36.7219 \pm 0.0010$ (2 SD, n = 5). Results for external standards AGV-2 and BCR-2 overlap with recommended values and are listed in the online supporting information.

Figure 2. Typical examples of the Kolumbo volcanic rocks: photomicrographs in (a-d) plain polarized light and (c-f) backscattered electron (BSE) images: (a) K2 pumice sample, showing a cluster of euhedral plagioclase and biotite phenocrysts in a glassy, vesicular matrix; (b) Kolumbo lava sample with a microlite groundmass with seriate texture plagioclase and two partly resorbed hornblende phenocrysts with opacite rims; (c) Mafic inclusion in a K2 pumice sample with plagioclase and clinopyroxene in a quench texture groundmass of acicular hornblende and plagioclase. The plagioclase crystal in the top-center has a pronounced sieved textured core; (d) The fine-grained, chilled margin of a mafic enclave in the K2 pumice indicates rapid quenching as a result of its incorporation in a cooler silicic host; (e) 1650 AD pumice sample with a euhedral biotite and plagioclase phenocryst in a glassy, vesicular matrix; (f) The same mafic inclusion as shown in Figure 2c in which acicular hornblende (light grey) and plagioclase (mid grey) display a quenched, spherulitic texture with diktytaxitic voids (black). White specks are Fe-Ti-oxides. Note the absence of a chilled margin in this inclusion, in contrast with the one shown in Figure 2d.
Mineral and glass compositions of a K2 pumice and 1650 AD pumice sample were determined using JEOL JXA-8530F electron probe microanalyzer at the Dutch National Geological Facility, Utrecht University, at an acceleration voltage of 15 kV. For biotite, amphibole and pyroxene analyses, a beam current of 20 nA and focused spot were used. To prevent Na loss, the beam current was lowered to 10 nA and a spot size of 5 μm was employed for glass and plagioclase analyses. Results were normalized using an online φ(rZ) correction. All EMP results are provided in the online supporting information.

4. Results

4.1. Petrography of the Kolumbo Suite

The two pumice deposits exposed in the Kolumbo crater, the K2 and 1650 AD pumices, have similar petrographic features but are readily distinguishable. The 1650 AD products are white pumices with 40–70% round to elongated vesicles (<5 mm) and <5% plagioclase and biotite phenocrysts (Figure 2; see also Cantner et al. [2014]), while the K2 pumices are grey and contain considerably fewer and smaller vesicles (<1 mm). Both pumice units have a holohyaline groundmass and plagioclase is the dominant phenocryst phase (1–3 vol.%), along with common euhedral biotite (Figure 2). Fe-Ti-oxides comprise <1 vol.% and orthopyroxene, quartz and amphibole are rare phenocryst phases. Zircon and apatite occur as accessory phases that are hosted predominantly in plagioclase. Both the K2 and 1650 AD pumices contain cm-sized mafic inclusions (generally 0.2–2 cm) with a quench texture of acicular plagioclase and amphibole and larger phenocrysts (up to 500 μm) of plagioclase, clinopyroxene and rare amphibole (Figure 2). Plagioclase phenocrysts in the mafic inclusions display a wide variation in textures and often have sieve textured cores. The contacts between the inclusions and the host pumice are invariably sharp, but the mafic inclusions vary from angular to rounded; chilled margins are generally better developed in the rounded inclusions. The presence of chilled margins and the quenched, sometimes spherulitic, amphibole-plagioclase texture suggest that these inclusions originate as mafic enclaves that rapidly crystallized upon intrusion in the cooler host magma.

Several poorly defined intrusive bodies in the lower parts of the Kolumbo crater probably represent lavas or dykes intruded in the pumice deposits [Hübscher et al., 2015] and are therefore referred to as lava samples. The samples of the lava bodies typically have a porphyritic texture of plagioclase, clinopyroxene, amphibole, Fe-Ti-oxide and rare orthopyroxene phenocrysts set in a fine plagioclase microlite groundmass (Figure 2b). Amphibole in the lavas generally has an opacite reaction rim as a result of decompression and some plagioclase crystals display complex oscillatory zonation patterns that are not commonly seen in the pumices.

4.2. Glass Geochemistry

The major element compositions of the Kolumbo K2 and 1650 AD glasses are shown in two discrimination diagrams in Figure 3. Our results for the 1650 AD pumice agree well with those reported by Cantner et al.
apart from Na$_2$O contents that are $\sim$0.4 wt.% lower in our data set. This offset could be the result of Na-loss during our analyses, despite our best efforts to minimize Na-loss by using a larger spot size and lower beam current. As is evident from Figure 3, there is no discernible difference in major elements other than Na$_2$O between our results and those from Cantner et al. [2014].

Both K2 and 1650 AD glasses are rhyolitic in composition with SiO$_2$ contents of $\sim$75.5 wt.% (on a volatile-free basis). The two deposits cannot be distinguished on the basis of major element composition of the pumice glasses as the average compositions for the two samples are within analytical uncertainty (2 SD), although it could be argued that the K$_2$O content of the K2 pumice is somewhat higher (Figure 3b).

The Kolumbo glasses are clearly different from the glass compositions of products from the last three major Pli- nian eruptions of Santorini (Figure 3). In the recent volcanological record of Santorini, the 3.6 ka Minoan eruption has the most silicic glass composition: 73.4 $\pm$ 0.4 wt.% SiO$_2$ [Federman and Carey, 1980; Vinci, 1985]. The 26 ka Cape Tripiti [Fabbro et al., 2013] and 22 ka Cape Riva [Vinci, 1985; Wulf et al., 2002]
eruptions have both deposited pumices with lower glass SiO₂ contents. Hence, the Kolumbo glasses are significantly more evolved than those erupted during the recent explosive events on Santorini.

4.3. Mineral Geochemistry

The major element composition of minerals in the 1650 AD and K2 pumice is shown in Figure 4 and compared with data for Santorini. Plagioclase phenocrysts in the 1650 AD and K2 pumices are similar in composition with An% between 19 and 22. Higher An% plagioclase in these samples is found in the mafic inclusions in which plagioclase cores range up to 93 An%. Acicular amphibole in these mafic inclusions is unusually SiO₂-poor magnesiohastingsite to tschermakitic pargasite with Mg# (assuming total Fe as Fe²⁺) between 50 and 70 and 11–14 wt.% Al₂O₃. In comparison, the Akrotiri rhyodacites, the only unit on Santorini with a significant proportion of hornblende (see section 5.1.2), show a bimodal distribution of amphibole compositions with more SiO₂-rich and Al₂O₃-poor amphibole residing in the rhyodacitic host and more SiO₂-poor and Al₂O₃-rich amphibole present in the mafic enclaves (Figure 4) [Mortazavi and Sparks, 2004]. Kolumbo amphibole roughly overlaps in composition with amphibole in the Akrotiri enclaves. Clinopyroxene in mafic inclusions and mafic crystal clots in the K2 pumice has high Al₂O₃ contents up to 9 wt.% at Mg# between 69 and 81, with generally lower Al₂O₃ contents in crystal rims. Biotite compositions in the K2 and 1650 AD pumice are distinct and can be differentiated on the basis of higher MgO content in 1650 AD biotites (6.5–7.0 wt.% compared to 5.0–6.2 wt.% in the K2 pumice).

4.4. Whole Rock Geochemistry

The whole rock geochemical composition of the Kolumbo suite is shown in Figures 5–8 where the data are compared with data for Santorini. Plagioclase phenocrysts in the 1650 AD and K2 pumices are similar in composition with An% between 19 and 22. Higher An% plagioclase in these samples is found in the mafic inclusions in which plagioclase cores range up to 93 An%. Acicular amphibole in these mafic inclusions is unusually SiO₂-poor magnesiohastingsite to tschermakitic pargasite with Mg# (assuming total Fe as Fe²⁺) between 50 and 70 and 11–14 wt.% Al₂O₃. In comparison, the Akrotiri rhyodacites, the only unit on Santorini with a significant proportion of hornblende (see section 5.1.2), show a bimodal distribution of amphibole compositions with more SiO₂-rich and Al₂O₃-poor amphibole residing in the rhyodacitic host and more SiO₂-poor and Al₂O₃-rich amphibole present in the mafic enclaves (Figure 4) [Mortazavi and Sparks, 2004]. Kolumbo amphibole roughly overlaps in composition with amphibole in the Akrotiri enclaves. Clinopyroxene in mafic inclusions and mafic crystal clots in the K2 pumice has high Al₂O₃ contents up to 9 wt.% at Mg# between 69 and 81, with generally lower Al₂O₃ contents in crystal rims. Biotite compositions in the K2 and 1650 AD pumice are distinct and can be differentiated on the basis of higher MgO content in 1650 AD biotites (6.5–7.0 wt.% compared to 5.0–6.2 wt.% in the K2 pumice).

**Figure 5.** Whole rock major element variation diagrams for Kolumbo compared with Santorini [this study; Druitt et al., 1999; Zellmer et al., 2000; Mortazavi and Sparks, 2004; Bailey et al., 2009; Kirchenbaur et al., 2012; Fabbro et al., 2013; Druitt, 2014; Klaver et al., 2016a]. For Santorini, the 197 BC to 1950 AD Kameni dacites (dark grey triangles) and 3.6 ka Minoan Tuff (light grey triangles), which are roughly synchronous with the Kolumbo deposits, are highlighted. The K₂O versus SiO₂ diagram is after Le Maitre et al. [1989].

eruptions have both deposited pumices with lower glass SiO₂ contents. Hence, the Kolumbo glasses are significantly more evolved than those erupted during the recent explosive events on Santorini.
Figure 6. Variation diagrams of selected trace elements versus SiO$_2$ for the Kolumbo sample suite in comparison with the range of Santorini volcanic products. For Santorini, the recent Kameni dacites (dark grey triangles) and Minoan Tuff (light grey triangles) are highlighted. Symbols and data sources as in Figure 5.

Figure 7. N-MORB normalized multielement abundance diagram of the Kolumbo samples in comparison with the recent Santorini Kameni dacites; N-MORB values from Sun and McDonough [1989]. The light blue field represents the total variation of the K2 and 1650 AD pumices combined; these two pumice suites are indistinguishable in this diagram.
and Minoan Tuff samples are highlighted in all figures. The full geochemical data for the Kolumbo samples, as well as the new Santorini data, are provided in the online supporting information.

4.4.1. Major and Trace Elements

Figures 5 and 6 show the variation of a selection of major and trace elements in the Kolumbo suite. The 1650 AD and K2 pumices are rhyolites with 72 to 74 wt.% SiO₂. Compared to the Minoan Tuff, which is the most evolved unit on Santorini with 69–71.5 wt.% SiO₂ [e.g., Druitt et al., 1999; Druitt, 2014], the Kolumbo pumices have higher SiO₂, Na₂O and K₂O, and lower MgO, FeO*, TiO₂, Al₂O₃ and CaO contents (Figure 5). Kolumbo lavas are basaltic to andesitic in composition and overlap with Santorini for MgO and K₂O contents, but the andesitic lavas are characterized by a higher Al₂O₃ concentration (17.7 wt.%). The silica content of the mafic enclave in a K2 pumice sample is similar to the Kolumbo lavas, but is distinct in MgO, Al₂O₃ and trace element concentrations. In terms of major element composition, the K2 and 1650 AD pumices are similar but not identical. The 1650 AD pumices are marginally lower in SiO₂ and Al₂O₃, but Na₂O and K₂O contents are the main difference: K2 pumices have lower alkali concentrations, even though the K2 glasses are characterized by higher K₂O contents (Figure 3).

Trace element concentrations are mostly uniform for the two pumice groups except for a more pronounced difference in Sc and Rb contents (Figure 6). A single 1650 AD pumice sample retrieved from the hydrothermal field on the crater floor (Figure 1c) has an anomalously high Pb content (23 ppm, ~8 ppm higher than the other samples) that is likely related to hydrothermal alteration. The trace element characteristics of the Kolumbo suite are distinct from the large variation shown by the Santorini volcanic rocks. The most notable differences are lower Zr, La and Th contents in the Kolumbo lavas and pumices compared to Santorini. In contrast, Sr contents are much higher in the Kolumbo andesitic lavas compared to Santorini andesites (ca. 550 ppm versus 200–300 ppm respectively). Niobium contents of the Kolumbo pumices (18–20 ppm) are elevated compared to both the Santorini rhyolites and Kameni dacites (<13 ppm), although the pumices fall on an extrapolated trend defined by the less evolved Santorini samples. Whereas the Zr content of the Kolumbo pumices is lower than in the Minoan pumice (ca. 130 versus 300 ppm respectively), it is similar to Santorini’s hornblende-bearing Akrotiri rhyodacites with ca. 100 ppm Zr at 69–71 wt.% SiO₂ [Mortazavi and

Figure 8. Sr-Nd-Hf-Pb isotope diagrams for Kolumbo compared to data for Santorini (grey circles) with the recent Kameni dacites (dark grey triangles) and Minoan Tuff (light grey triangles) highlighted. Data sources as in Figure 5. For scaling purposes, the Santorini data (206Pb/204Pb > 18.8) are omitted from the Pb diagrams, but are shown in Figures 10 and 12. The terrestrial array (TA) in the 176Hf/177Hf versus 143Nd/144Nd diagram is from Vervoort et al. [2011].

and Minoan Tuff samples are highlighted in all figures. The full geochemical data for the Kolumbo samples, as well as the new Santorini data, are provided in the online supporting information.
Sparks, 2004]. The trace element data furthermore show that the Kameni dacites are also distinct from the main Santorini trend and generally have lower trace element abundances than the older volcanic units of Santorini at similar SiO\textsubscript{2} content [e.g., Huijsmans et al., 1988; Zellmer et al., 2000].

The difference between the Kolumbo pumices and Kameni dacites is highlighted in an N-MORB normalized multi-element abundance diagram (Figure 7). Both sample suites have a trace element pattern typical of subduction zone magmas with negative Nb-Ta and Ti anomalies, pronounced LILE over HFSE enrichment and a large, positive Pb anomaly compared to N-MORB. The Kameni dacites have higher concentrations of less incompatible elements, such as middle to heavy rare earth elements (MREE and HREE), Zr and Y, while LILE concentrations are roughly similar. In addition, both the Kolumbo and the Kameni samples have a negative Ba anomaly and a small but distinct positive Zr-Hf anomaly relative to Sm.

4.4.2. Sr-Nd-Hf-Pb Isotopes

The Kolumbo pumices display a limited range in Pb isotope compositions (206\textsubscript{Pb}/204\textsubscript{Pb} 18.725–18.745) that is lower compared to Santorini (206\textsubscript{Pb}/204\textsubscript{Pb} ~18.8–19.0; Figures 8, 10 and 12). In terms of 87\textsubscript{Sr}/86\textsubscript{Sr}, 143\textsubscript{Nd}/144\textsubscript{Nd} and 176\textsubscript{Hf}/177\textsubscript{Hf}, there is more overlap between Kolumbo and the range displayed by the Santorini volcanic rocks. Within the Kolumbo suite, the lavas and K2 enclave have lower 87\textsubscript{Sr}/86\textsubscript{Sr}, 207\textsubscript{Pb}/204\textsubscript{Pb} and 208\textsubscript{Pb}/204\textsubscript{Pb} and higher 143\textsubscript{Nd}/144\textsubscript{Nd} and 176\textsubscript{Hf}/177\textsubscript{Hf}, and are thus closer to depleted mantle compared to the pumices, but 206\textsubscript{Pb}/204\textsubscript{Pb} is higher in these samples and the basaltic lava 206\textsubscript{Pb}/204\textsubscript{Pb} = 18.815 overlaps with the least radiogenic Santorini values (Figures 10 and 12). The andesitic lava samples fall on the terrestrial Nd-Hf isotope array of Vervoort et al. [2011], whereas the Kolumbo basaltic lava, pumices and Santorini samples have lower 143\textsubscript{Nd}/144\textsubscript{Nd} for a given 176\textsubscript{Hf}/177\textsubscript{Hf}. The K2 and 1650 AD pumices have identical Nd, Hf and Pb isotope compositions with the exception of two 1650 AD pumices; one of which has a higher Pb content (Figure 6) and more radiogenic Pb isotope composition whilst the other has lower 206\textsubscript{Pb}/204\textsubscript{Pb} and 208\textsubscript{Pb}/204\textsubscript{Pb} but overlapping 207\textsubscript{Pb}/204\textsubscript{Pb}. In terms of 87\textsubscript{Sr}/86\textsubscript{Sr}, however, the two Kolumbo pumice suites show considerable variation and the 1650 AD pumices have a more radiogenic composition (0.7048–0.7051) than the K2 pumices (0.7042–0.7044). As 87\textsubscript{Sr}/86\textsubscript{Sr} shows a well-defined positive correlation with Na\textsubscript{2}O content for the rhyolitic pumices (not shown), the higher 87\textsubscript{Sr}/86\textsubscript{Sr} in the 1650 AD pumices likely reflects seawater addition to the more vesicular 1650 AD pumices.

5. Discussion

5.1. Comparison Between Kolumbo and Recent Santorini

The occurrence within the same extension-related basement fault zone along the CSK tectonic line and short distance between the two volcanic centers (15 km from the center of Santorini caldera to the center of the Kolumbo crater; Figure 1) suggest that Kolumbo and Santorini could be different surface expressions of the same volcanic system. This is supported by the proposed lateral extension of a shallow (5–7 km) crustal hot zone underneath Kolumbo toward the magmatic system of Santorini [Dimitriadis et al., 2010]. To investigate a possible relationship between the crustal plumbing system of Santorini and Kolumbo, we will address some first-order observations that arise from a comparison of the petrographic and geochemical characteristics of the Kolumbo suite and recent Santorini products.

5.1.1. A Present-Day, Shallow Connection?

The 1650 AD eruption of Kolumbo occurred contemporaneously with the intermittent volcanic activity in the center of the Santorini caldera over the last ~2 kyr. Dacitic flows erupted from the Nea Kameni vent in the Santorini caldera in 1570–1573 AD and 1707–1711 AD [Druitt et al., 1999], hence enveloping the 1650 AD eruption of Kolumbo. The rhyolitic 1650 AD pumices are different in terms of petrography and geochemistry from the Kameni dacites, which are very homogeneous and do not display significant temporal variation over the last ~2 kyr [Barton and Huijsmans, 1986; Zellmer et al., 2000]. In contrast with the abundance of biotite and amphibole in the Kolumbo pumices and enclaves, the Kameni dacites are characterized by an anhydrous mineral assemblage dominated by plagioclase, clinopyroxene and orthopyroxene, and a complete absence of amphibole in quenched mafic enclaves hosted in the dacites [Martin et al., 2006]. The geochemical differences are even more pronounced; the Kolumbo pumices are significantly more evolved at 72–74 wt.% SiO\textsubscript{2} and have higher alkali element abundances (Figure 5), which is emphasized by distinct trace element patterns (Figures 6 and 7) and isotope compositions (Figure 8). Hence, it is highly unlikely that the 1650 AD pumice are derived from the same shallow magmatic system from which the Kameni dacites are tapped. This is supported by the distinct He isotope composition of gasses emitted.
from vents in the Kameni islands and the Kolumbo hydrothermal system (3–4 Ra and 7.0–7.1 Ra, respectively) [Rizzo et al., 2016]. A scenario in which the 1650 AD pumices represent evolved residual magma of the 3.6 ka rhyodacitic Minoan eruption can also be precluded on the basis of large trace element and isotope differences (Figures 6 and 8). Although $^{87}$Sr/$^{86}$Sr, $^{143}$Nd/$^{144}$Nd and $^{176}$Hf/$^{177}$Hf values overlap, in particular lower $^{206}$Pb/$^{204}$Pb in the Kolumbo pumices compared to the recent Santorini products (Figure 10) strongly argues against a direct genetic relationship between the Minoan Tuff or Kameni dacites and the 1650 AD pumice. On the basis of these observations, it can be concluded that the Kolumbo 1650 AD pumice is not related to the recent Santorini volcanic products and is derived from a reservoir with geochemically distinct magma. Given the strong similarity in petrography and geochemistry of the K2 and 1650 AD pumices, it is likely that the K2 pumices are derived from the same distinct magmatic system as the 1650 AD deposits and are also unrelated to Santorini. Hence, the new geochemical data do not support the proposed connection between the magmatic systems of Kolumbo and Santorini [Dimitriadis et al., 2010]. Whether the Kolumbo and Santorini magmas are derived from the same mantle source but have obtained their geochemical differences through distinct crustal differentiation processes, is discussed in sections 5.2 and 5.3.

5.1.2. Amphibole and Biotite in the Kolumbo Suite

The main petrographic feature of the Kolumbo suite is the ubiquitous presence of biotite in the K2 and 1650 AD pumices. Amphibole is a common phase in the lavas and enclaves, and occurs sporadically in the pumices. Both these phases are rare in Santorini; biotite is absent altogether and amphibole occurs only as a significant phenocryst phase in the $>$550 ka Akrotiri rhyodacites, the oldest volcanic unit on Santorini that is distinct from all younger Santorini volcanic deposits in terms of petrography and geochemistry [Mortazavi and Sparks, 2004]. In the younger Santorini deposits, trace amounts of amphibole occur in Lower Pumice 2 [Gertisser et al., 2009], amphibole occurs as rare inclusions in orthopyroxene in the Minoan pumice [Cottrell et al., 1999] and hornblende-bearing microphenocryst-rich pumices and hornblende-diorites were coerupted with the Minoan Tuff [Druitt, 2014].

Despite the common absence of amphibole phenocrysts in arc lavas worldwide, the vast majority of arc volcanic suites display geochemical evidence for cryptic amphibole fractionation [Davidson et al., 2007, 2013; Smith, 2014] and the role of amphibole as a major phase in controlling the differentiation of hydrous arc magmas is suggested by a number of experimental studies [e.g., Sisson and Grove, 1993; Alonso-Perez et al., 2009]. Figure 9 displays the variation of Y and Dy/Yb with SiO$_2$ content. As Y and Dy are compatible in amphibole but largely incompatible in a typical anhydrous assemblage (Pl+Cpx+Ol+Opx), these parameters are indicative of the presence of amphibole as a fractionating phase [e.g., Davidson et al., 2007]. The less evolved Santorini volcanic rocks ($<$65 wt.% SiO$_2$) are characterized by a general increase in Y content and subhorizontal Dy/Yb that is consistent with largely amphibole-free differentiation, as also concluded by Mortazavi and Sparks [2004] and Elburg et al. [2014]. Only the Santorini (rhyo)dacites ($>$65 wt.% SiO$_2$) are characterized by decreasing Y contents and Dy/Yb with SiO$_2$, suggesting a modest amphibole control in the most evolved rocks [Elburg et al., 2014]. The Kolumbo pumices have subchondritic Dy/Yb and low Y

![Figure 9.](image-url)
Moreover, the large difference in Dy/Yb between the lavas and pumices, high Dy/Yb of the basaltic lava and uniformly low Y contents suggest amphibole control over the entire range in SiO₂ contents rather than derivation from a low-Dy/Yb, low-Y source for the Kolumbo suite. The Kolumbo K2 and 1650 AD pumices overlap in Y content with the >550 ka amphibole-bearing Akrotiri rhyodacites. Due to the lack of high-quality Dy and Yb data, however, it is not possible to unequivocally distinguish between amphibole fractionation and other processes leading to low Y contents in the Akrotiri rhyodacites. Hence, Kolumbo and Santorini are characterized by two contrasting differentiation trends, with Kolumbo showing clear geochemical evidence for a key role of amphibole in its petrogenesis, while Santorini appears to have evolved largely through fractional crystallization of an anhydrous mineral assemblage [e.g., Huijsmans et al., 1988; Druitt et al., 1999] with no evidence for amphibole fractionation at <65 wt.% SiO₂. The point that should be stressed is that the amphibole-present differentiation trend shown by Kolumbo is typical of most arc volcanoes worldwide and that Santorini is the exception [Elburg et al., 2014]. The general absence of amphibole in the Santorini suite is likely the result of crystallization under hotter conditions compared to the Akrotiri rhyodacites and, by inference, Kolumbo [Druitt et al., 1999; Cadoux et al., 2014; Andújar et al., 2015].

5.2. Role of Crustal Contamination in the Evolution of Kolumbo

Contamination of arc magmas through assimilation of wall rock lithologies or mixing with crustal melts is a common process and can have a profound influence on the trace element and isotope composition of these magmas [e.g., Hildreth and Moorbath, 1988; Annen et al., 2006; Bezard et al., 2014]. Hence, before discussing potential variation in the Kolumbo and Santorini mantle sources, it is essential to assess the influence of assimilation of arc crust in the Kolumbo suite. Correlation between radiogenic isotopes and indices of magma differentiation such as SiO₂ and MgO are taken as strong evidence for assimilation of arc crust, mainly because variations in recycled crustal components derived from the subducting slab do not readily exert a strong control on the major element geochemistry of arc lavas [Davidson, 1987; Thirlwall et al., 1996; Bezard et al., 2014]. Figure 10a displays the variation in ⁸⁷Sr/⁸⁶Sr with SiO₂ content for the Kolumbo samples in comparison with the range...
displayed by Santorini. In the Kolumbo suite, higher $^{87}\text{Sr}/^{86}\text{Sr}$ in the 1650 AD pumices relative to the K2 samples likely reflects seawater addition. Apart from this secondary effect, the Kolumbo suite shows a general increase of $^{87}\text{Sr}/^{86}\text{Sr}$ with $\text{SiO}_2$ from the lavas to the K2 pumices. Santorini is also characterized by an increase in $^{87}\text{Sr}/^{86}\text{Sr}$ with magmatic differentiation, indicative of open-system differentiation and contamination of the magmas by arc crust. This is corroborated by decreasing $^{143}\text{Nd}/^{144}\text{Nd}$ and $^{176}\text{Hf}/^{177}\text{Hf}$, and increasing $^{207}\text{Pb}/^{204}\text{Pb}$ with $\text{SiO}_2$ content for Kolumbo (not shown) and Santorini [e.g., Druitt et al., 1999; Zellmer et al., 2000].

Given the limited systematic variability in their $\text{Sr}$, $\text{Nd}$, or $\text{Hf}$ isotope composition, it is not possible to distinguish between different potential assimilants on the basis of these isotope systems. Pb isotopes, on the other hand, have the potential to make a general distinction between assimilation of upper- and lower crust in the Santorini volcanic field. Pre-Alpine orthogneisses that are exposed in a core complex on the island of los [e.g., Thomson et al., 2009], ca. 20 km N of Santorini and Kolumbo (Figure 1) are characterized by high-time-integrated Th/U and have therefore evolved to high $^{206}\text{Pb}/^{204}\text{Pb}$ and moderate $^{207}\text{Pb}/^{204}\text{Pb}$ at relatively low $^{206}\text{Pb}/^{204}\text{Pb}$. These los gneisses are generally interpreted to constitute the lower crust of the Santorini volcanic field [e.g., Bonneau, 1984; Druitt et al., 1999; Kilias et al., 2013]. In contrast, the shallow calc-silicate basement that is exposed, for instance, on Mt. Profitis Ilias on Santorini is characterized by higher $^{206}\text{Pb}/^{204}\text{Pb}$ and lower $^{207}\text{Pb}/^{204}\text{Pb}$ and $^{208}\text{Pb}/^{204}\text{Pb}$ (Figure 10b). In a $^{208}\text{Pb}/^{204}\text{Pb}$ versus $^{206}\text{Pb}/^{204}\text{Pb}$ diagram, Santorini is situated at the radiogenic edge of an array defined by the Aegean arc volcanic rocks [Elburg et al., 2014]: the “main Aegean array” in Figure 10b. Upper crustal calc-silicate basement samples overlap in Pb isotope composition with the most radiogenic Santorini samples, suggesting that assimilation of upper crustal material is predominant in Santorini [e.g., Druitt et al., 1999; Elburg et al., 2014]. The Kolumbo samples, however, project away from the main Aegean array toward higher $^{208}\text{Pb}/^{204}\text{Pb}$ and the field defined by the lower crustal basement. On this basis, we relate the higher $^{207}\text{Pb}/^{204}\text{Pb}$, $^{207}\text{Pb}/^{204}\text{Pb}$ and $^{87}\text{Sr}/^{86}\text{Sr}$ at lower $^{143}\text{Nd}/^{144}\text{Nd}$ and $^{206}\text{Pb}/^{204}\text{Pb}$ of the K2 and 1650 AD pumices, compared to the Kolumbo lavas, to the preferential assimilation of pre-Alpine, lower crustal basement. The involvement of lower crustal basement is uncommon in the Aegean arc and such a signature is absent on Santorini and the eastern volcanic center Nisyros; in the west, the Saronic Gulf volcanic centers also display higher $^{208}\text{Pb}/^{204}\text{Pb}$ at given $^{206}\text{Pb}/^{204}\text{Pb}$, but this is coupled to more crustal $^{87}\text{Sr}/^{86}\text{Sr}$ and $^{143}\text{Nd}/^{144}\text{Nd}$ [Elburg et al., 2014].

Despite that $^{207}\text{Pb}/^{204}\text{Pb}$ and $^{208}\text{Pb}/^{204}\text{Pb}$ in the Kolumbo suite are elevated compared to the main Aegean array due to crustal assimilation (Figure 10), these values are lower than the majority of the Santorini samples. Relating the lower $^{206}\text{Pb}/^{204}\text{Pb}$ of Kolumbo to contamination of primitive Santorini magmas ($^{206}\text{Pb}/^{204}\text{Pb} > 18.88$) with lower crustal basement is thus inconsistent with $^{207}\text{Pb}/^{204}\text{Pb}$ and $^{208}\text{Pb}/^{204}\text{Pb}$ of Kolumbo (Figure 10b). This is supported by the high $^{143}\text{Nd}/^{144}\text{Nd}$ (0.51282) and low $^{87}\text{Sr}/^{86}\text{Sr}$ (0.7036) of the Kolumbo lavas that rule out a large degree of contamination. Hence, Pb isotopes indicate that the distinct crustal differentiation trends of Kolumbo and Santorini are the result of the preferential assimilation of lower and upper crust, respectively, but that this difference in assimilants fails to account for the full Pb isotope variability in primitive Kolumbo and Santorini samples. Substantial variation in $^{206}\text{Pb}/^{204}\text{Pb}$ (18.750–18.815) and $^{176}\text{Hf}/^{177}\text{Hf}$ (0.28296–0.28300) at constant $^{207}\text{Pb}/^{204}\text{Pb}$, $^{208}\text{Pb}/^{204}\text{Pb}$, $^{87}\text{Sr}/^{86}\text{Sr}$ and $^{143}\text{Nd}/^{144}\text{Nd}$ in the Kolumbo lavas is also inconsistent with any plausible assimilant and hence we ascribe this to variation in primary magmas delivered to the magmatic systems of Kolumbo and Santorini, which we will investigate in more detail in the next section.

### 5.3. A Distinct Source for Kolumbo

#### 5.3.1. HFSE Systematics

The trace element diagrams in Figure 6 highlight that the most pronounced differences between Kolumbo and Santorini are found in the high-field strength elements (HFSE). These variations partly result from contrasting crustal differentiation processes as illustrated by the Zr versus $\text{SiO}_2$ trend in Figure 6. The Kolumbo suite displays a minor decrease in Zr concentrations from the lavas to the pumices that is similar to Santorini’s Akrotiri rhyodacites, whereas the other Santorini deposits show a steady increase in Zr with $\text{SiO}_2$. Niobium systematics display the most striking difference between the evolution trends of Kolumbo and Santorini. Figure 11a illustrates that the Kolumbo suite shows a stronger increase in Nb/Yb with $\text{SiO}_2$ compared to Santorini, consistent with the on average higher Nb contents in the Kolumbo pumices. This diagram again provides strong evidence against a direct relationship between the Kolumbo pumices and the recent Kameni dacites and Minoan Tuff as we envisage that there is no plausible fractional crystallization
process that can produce such a marked increase in Nb/Yb at similar SiO2 content. Differences in fractionating mineral assemblages are the likely explanation for the sharp increase in Nb/Yb with SiO2 as well as with Th (Figure 11b) in the Kolumbo suite compared to Santorini. Although the presence of amphibole has imparted a distinct geochemical fingerprint on the Kolumbo suite (see section 5.1.2), the partition coefficient for Nb in amphibole is an order of magnitude higher than for Th [e.g., Brenan et al., 1995] and thus amphibole fractionation should result in a smaller increase in Nb/Yb with Th content. A more plausible explanation is that the Nb content is buffered by abundant Fe-Ti-oxide fractionation in the Santorini suite [e.g., Huijms et al., 1988; Andujar et al., 2015]. Alternatively, removal of zircon could present a sink for Th in the Kolumbo suite resulting in the decoupling of Nb/Th, but this fails to explain the high absolute Nb concentrations in the Kolumbo samples.

In addition to the stronger increase in Nb/Yb with SiO2 for the Kolumbo suite, the Kolumbo lavas appear to have higher Nb/Yb than Santorini samples at any given SiO2 content. To investigate whether the higher Nb/Yb reflects a source feature or can be explained by the addition of a larger amount of subducted sediments, Nb/Yb is shown against Th content and 143Nd/144Nd in Figures 11b and 11c where only the most primitive (<60 wt.% SiO2) samples are included. Bailey et al. [2009] identified three separate magmatic series on Santorini based on the Nb content of the most primitive samples within each suite. On the basis of correlations between Nb content and Sr-Nd-Pb isotopes, with the high-Nb series corresponding to more enriched isotope compositions, the three magmatic series are interpreted as the result of an increasing contribution of recycled sediments from the low-Nb to the high-Nb series [Bailey et al., 2009]. This interpretation is in good agreement with the suggestion of Kirchenbaur and Münker [2015] that the HFSE budget in primitive Santorini samples is dominated by fluids and melts derived from subducted sediments. In addition, MORB-like Nb/Ta and Zr/Hf exclude HFSE fractionation by residual HFSE-rich phases in the mantle source of Santorini [Kirchenbaur and Münker, 2015]. Thus, the most primitive Santorini samples (<55...
wt.% SiO$_2$) overlap with N-MORB in Nb/Yb and the coupled increase in Nb/Yb and Th content and decrease in $^{143}$Nd/$^{144}$Nd from the low-Nb to the high-Nb series (Figure 11) is consistent with sediment addition to an N-MORB mantle source [Zellmer et al., 2000; Bailey et al., 2009; Kirchenbaur et al., 2012; Kirchenbaur and Münker, 2015].

The Kolumbo suite has an extrapolated Nb concentration of 5–7 ppm at 53 wt.% SiO$_2$, which overlaps with the medium-Nb (mean 4.7 ppm Nb) and high-Nb series (mean 7.1 ppm Nb) of Bailey et al. [2009]. Nb/Yb also overlaps with the high-Nb series of Santorini, but Th contents are lower and in particular $^{143}$Nd/$^{144}$Nd is higher in the primitive Kolumbo samples. This suggests that high Nb/Yb of Kolumbo is not the result of a large subducted sediment contribution as in the high-Nb series of Santorini, but that it more likely reflects a mantle source feature. As Nb/Yb in the Kolumbo suite approaches values for Atlantic E-MORB (Figure 11b), we argue that the higher Nb/Yb points to derivation from a more enriched mantle source compared to Santorini. This is supported by lower Zr/Nb (ca. 12 versus >25; Figure 12) and higher Dy/Yb (1.16 versus 1.24; Figure 9), Nb/Ta (15.5–18 versus 14–16) and Zr/Hf (39–44 versus 35–40) of Kolumbo compared to Santorini.

Instead, Kolumbo shares many HFSE and isotope characteristics with Nisyros (Figures 11 and 12), the easternmost active volcanic center of the Aegean arc, ca 150 km to the east.

5.3.2. Pb Isotopes

The most pronounced isotopic difference between Kolumbo and Santorini is found in Pb isotopes. Kolumbo has lower $^{206}$Pb/$^{204}$Pb (18.73–18.81) compared to Santorini (18.8–19.0, mostly >18.88) and in particular the recent Kameni dacites and the Minoan Tuff (~18.95; Figure 12). As discussed in section 5.2, Pb isotopes indicate that the distinct crustal differentiation trends of Kolumbo and Santorini are the result of the preferential assimilation of lower- and upper crust, respectively. This difference in assimilants fails to account for the full Pb isotope variability in primitive Kolumbo and Santorini magmas. Here we will test whether this difference can be explained by mantle source heterogeneity as concluded on the basis of the HFSE systematics.

In the case of Santorini, Nd-Pb isotope and trace element systematics can be explained by the addition of 0.5–5% subducting Eastern Mediterranean Sea sediments [Klaver et al., 2015] to a depleted N-MORB mantle source [Bailey et al., 2009; Kirchenbaur and Münker, 2015; Klaver et al., 2016a]. Figure 12 shows a mixing model between a depleted mantle source and subducting sediments that is adapted from Klaver et al. [2016a]. This model fails to account for the composition of most of the Kolumbo samples as these are displaced to lower $^{143}$Nd/$^{144}$Nd compared to the mixing lines. In addition to the HFSE and $^{143}$Nd/$^{144}$Nd evidence, another argument against sediment addition is the combination of low Zr/Nb and low $^{206}$Pb/$^{204}$Pb in the Kolumbo lavas (Figure 12b). Sediment addition will result in a decrease in Zr/Nb from typical N-MORB values.
trigger for both the K2 and 1650 AD eruption injected into the cooler silicic reservoir. This suggests that mafic injections probably acted as an eruption amphibole and plagioclase, suggesting that they formed through quenching of hydrous, mafic melts make some inferences on the magmatic system of Kolumbo and the petrogenesis of the rhyolitic pumices.

The new petrographic and whole rock and mineral geochemical data of the Kolumbo suite can be used to

5.4. Petrogenesis of the Kolumbo Suite

The new petrographic and whole rock and mineral geochemical data of the Kolumbo suite can be used to make some inferences on the magmatic system of Kolumbo and the petrogenesis of the rhyolitic pumices. Both the 1650 AD and K2 pumices contain abundant cm-sized mafic inclusions with a texture of acicular amphibole and plagioclase, suggesting that they formed through quenching of hydrous, mafic melts injected into the cooler silicic reservoir. This suggests that mafic injections probably acted as an eruption trigger for both the K2 and 1650 AD eruption [Sparks et al., 1977; Cantner et al., 2014]. Contacts between the mafic inclusions and the rhyolitic host vary from rounded to angular and chilled margins are poorly developed in the more angular inclusions. The latter likely represent fragments of larger mafic enclaves, possible related to a previous episode of mafic melt injection, which were fragmented and dispersed in the rhyolitic host shortly prior to or during eruption. Small crystal clots consisting of clinopyroxene and plagioclase crystals that are present in the 1650 AD and K2 pumices likely originate in the same way [cf. Humphreys et al., 2009; Braschi et al., 2014]. The low Cr and Ni contents and andesitic composition of the analyzed mafic inclusion in the K2 pumice indicate that it is not a primitive melt and underwent differentiation and/or significant mixing with the rhyolitic host. Acicular amphibole and plagioclase in the mafic inclusions likely formed as a response to rapid cooling upon injection into the rhyolitic melt. Clinopyroxene macrocrysts in the mafic inclusion and in crystal clots, however, probably represent material that crystallized from the mafic melt at depth prior to its rise to the shallower rhyolitic reservoir. The high Al content of these clinopyroxenes (up to 9 wt.% Al₂O₃; Figure 4) suggests that they crystallized from a melt with a high Al₂O₃ content. Experimental studies have demonstrated that the high H₂O content of arc magmas leads to the suppression of plagioclase crystallization and promotes crystallization of olivine+clinopyroxene±spinel wherlite cumulates at lower crustal pressures, thereby driving the derivative liquid to a high-Al basalt composition [e.g., Sisson and Grove, 1993; Müntener et al., 2001; Pichavant and Macdonald, 2007]. Due to the absence of aluminous fractionating phases, clinopyroxene will become progressively Al-rich with differentiation, resulting in a
new correlation between Al content and Mg # in cpx (Figure 4). Indeed, such trends are shown by clino-
pyroxene in arc-root cumulate complexes [e.g., Jagoutz et al., 2007]. Hence, we assert that the Al-rich nature of
the Kolumbo clinoxyroxene macrocrysts attests to a differentiation history in a lower crustal reservoir
under hydrostatic conditions, resulting in the formation of wehrlite cumulates and the generation of high-Al
derivative liquids. The andesitic Kolumbo lavas are inferred to have formed through this process as well, given
their high Al2O3 and Sr contents (Figures 5 and 6).

We argue that the rhyolitic Kolumbo pumices are evolved liquids that formed through differentiation of these
high-Al, hydrous arc magmas at depth. Annen et al. [2006] have shown that highly evolved, hydrous arc magmas
are generated through prolonged crystal fractionation in a lower crustal reservoir, potentially in combination
with mixing with crustal melts. The silicic melts will rise through the crust and stall upon degassing, but can be made eruptible by means of the injection of hot mafic melts. Such a scenario is proposed for the
Akrotiri rhyodacites by Mortazavi and Sparks [2004], with which the Kolumbo pumices share many geochemi-
cal and petrographic characteristics, most notably the presence of amphibole. Residual hornblende in the lower
crustal reservoir is capable of imparting the geochemical amphibole signature on the extracted silicic melts
[Davidson et al., 2007; Smith, 2014]. Moreover, assimilation of lower crust during deep differentiation is a plausible means of explaining the characteristic high 208Pb/204Pb of the Kolumbo pumices.

Our proposed model of the magmatic system of Kolumbo includes a dominant role for differentiation at
the base of the arc crust. Prolonged differentiation and minor hybridization with lower crustal melts pro-
duced the Kolumbo rhyolites, which rose near adiabatically and stalled upon degassing, to form a partly
solidified mush at ca. 5–7 km depth [Dimitriadis et al., 2010; Cannter et al., 2014]. Evolved, high-aluminium
basalts were the parental melts to the Kolumbo lavas, and similar melts were injected in the shallow rhyolit-
ic mush, resulting in the eruption of the inclusion-bearing Kolumbo pumices. Several questions, however,
remain unanswered. It is not clear to what extent the model can account for the geochemical similarity of
the K2 and 1650 AD pumices, in particular if the suggested ~140 kyr time gap between the two eruptions
[Hubscher et al., 2015] is correct. Future studies including radiometric dating of the K2 pumice and geo-
chemical data for the units between the K2 and 1650 AD pumices are proposed to further unravel the geo-
chemical and geodynamical evolution of Kolumbo submarine volcano.

6. Conclusions

This study reports the first trace element and Sr-Nd-Hf-Pb isotope data for volcanic products of Kolumbo
submarine volcano, situated 15 km to the NE of Santorini. Kolumbo hosts biotite-bearing rhyolitic pumices
(~73 wt.% SiO₂, ~4.2 wt.% K₂O) and amphibole-bearing basaltic to andesitic (52–60 wt.% SiO₂) lavas and
comagmatic mafic inclusions that were emplaced contemporaneously with the second explosive cycle of
Santorini. The rhyolitic pumices display petrographic evidence for differentiation in a lower crustal reservoir
in the form of high-Al clinoxyroxene relics, before being emplaced in a shallow (5–7 km) magma chamber.
As suggested by the presence of quenched mafic enclaves, injection of mafic melts was the likely trigger of
the explosive eruptions. A deep differentiation history is corroborated by a signature of high 208Pb/206Pb compared to Santorini, which is interpreted to result from preferential assimilation of lower crustal base-
ment. The stability of amphibole at depth has imparted a pronounced geochemical signature on the
Kolumbo suite, which is one of the key characteristics of subduction-zone magmatism but conspicuously
absent on Santorini. There are marked geochemical differences between Kolumbo and Santorini despite
their proximity. In particular, high Nb/Yb (3–4) and low Zr/Nb (12–15), 206Pb/204Pb (~18.75) and 87Sr/86Sr
(~0.7036) at similar 143Nd/144Nd (~0.51283) for primitive Kolumbo samples are inconsistent with variable
amounts of subducting sediment addition or crustal contamination and likely reflect a source feature.
Kolumbo shares this signature with Nisyros, a volcanic center ~150 km to the east that is influenced by the
presence of an enriched mantle component in its source. On the basis of the similarity, we propose that
the distinct geochemical signature of Kolumbo is imprinted by variations in the mantle wedge underneath
the Santorini volcanic field. Thus, despite the close temporal and spatial association of the two volcanic cen-
ters, with a distance of only 15 km from crater to crater, we conclude that the Kolumbo suite is distinct from
the magmatic products of Santorini in its source and differentiation history. There is no evidence of a recent
shallow connection between the two plumbing systems or a genetic link relating the two suites to a com-
mon mantle source. The differences between Santorini and Kolumbo emphasize that the geochemical
variation within the Santorini volcanic field is larger than previously assumed. In addition, we recognize that arc volcanoes $\leq 15$ km apart can tap unrelated and distinct mantle sources, and that these distinct source signatures can be preserved through highly contrasting crustal evolution pathways.
