Myeloid-derived suppressor cells in gastrointestinal cancers: A systemic review

Maham Farshidpour, Monjur Ahmed, Shilpa Junna, Juanita L Merchant

Abstract

Gastrointestinal (GI) cancers are one of the most common malignancies worldwide, with high rates of morbidity and mortality. Myeloid-derived suppressor cells (MDSCs) are major components of the tumor microenvironment (TME). MDSCs facilitate the transformation of premalignant cells and play roles in tumor growth and metastasis. Moreover, in patients with GI malignancies, MDSCs can lead to the suppression of T cells and natural killer cells. Accordingly, a better understanding of the role and mechanism of action of MDSCs in the TME will aid in the development of novel immune-targeted therapies.

Key Words: Myeloid-derived suppressor cells; Gastrointestinal cancers; Immune checkpoint inhibitors; Tumor progression

MDSC MECHANISM OF ACTION

MDSCs are myeloid-derived heterogeneous cells with potent immune regulatory functions. They are derived from the myeloid lineage of immune cells that give rise to macrophages, granulocytes, and immature DCs. Monocytic MDSCs (M-MDSCs) and polymorphonuclear MDSCs (PMN-MDSCs) are the two major myeloid subsets of MDSCs. Phenotypically and morphologically, they are equivalent to monocytes and neutrophils, respectively (Table 1).

The process of myelopoiesis is driven by granulocyte-macrophage colony-stimulating factor (GM-CSF) in normal physiological conditions. Ultimately, GM-CSF and M-CSF induce the differentiation of granulocytes and macrophages from a common myeloid precursor that transforms into a common myeloblast. Myeloid...
DCs eventually arise from monocyctic as opposed to granulocytic lineages\[^{24}\]. However, the hypersecretion of these mediator factors during chronic inflammation and cancer leads to the generation of MDSCs\[^{26}\]. For example, inflammatory cytokines such as interleukin 6 (IL-6), IL-1\(\beta\), and IL-3 and C-X-C chemokine receptor type 4 (CXCR4) and CXCL12 can lead to the induction and proliferation of MDSCs in peripheral blood and tumor sites in cancer patients\[^{27}\]. The most important function of MDSCs is immunosuppression, mainly of target T cells (Figure 1)\[^{14}\].

Several \textit{in vitro} and \textit{in vivo} studies have documented the mechanisms underlying the immunosuppressive actions of MDSCs. Arginase 1 (ARG1), inducible nitric oxide (iNOS), reactive oxygen species, and reactive nitrogen species are important suppressive factors produced by MDSCs\[^{25}\]. Cao \textit{et al}\[^{26}\] reported that PMN-MDSCs store ARG1 and secrete it to the TME. ARG1 and NO\(_{\text{T}}\) activities lead to cellular depletion of L-arginine (referred to as L-arg), which is an essential substrate for T cell proliferation\[^{25,26}\]. Similar to T cells, depletion of L-arg also impairs the function of NK cells\[^{26}\].

In addition to immunosuppressive factors, MDSCs can overpower T cell functions by directly engaging with T cell inhibitory and apoptotic receptors. Activated MDSCs express high levels of Fas ligand (referred to as Fas L), programmed death-ligand 1 (PD-L1), and galectin-9. Subsequently, the interaction between these ligands with their receptors on T cells leads to T cell exhaustion \textit{via} PD-L1/programmed cell death protein 1 (PD-1) or T cell apoptosis through the Fas L/Fas and galectin-9/T cell immunoglobulin and mucin domain-3 pathways\[^{28}\]. Generally, M-MDSCs have more suppressive effects than PMN-MDSCs\[^{28}\]. Moreover, MDSCs can stimulate and recruit regulatory T cells (Tregs) to the TME\[^{29}\]. Tregs suppress anti-tumor immunity, and the interaction between MDSCs and Tregs create a strong blockade preventing cytotoxic immune cells from mounting an anti-tumor attack\[^{30}\]. Elevated levels of Tregs are associated with poor survival in patients with hepatocellular carcinoma (HCC) and pancreatic cancer\[^{30}\]. Regarding metastasis, MDSCs can promote angiogenesis by secreting IL-28 [interferon lambda (IFN-λ)] and matrix metalloproteinase (MMP)-9, promoting the invasion and migration of tumor cells\[^{30}\].

### MARKERS OF MDSCS IN PERIPHERAL BLOOD

MDSCs are categorized according to their phenotype, which includes several recognized surface markers, such as cluster of differentiation 33 (CD33), CD11b, or human leukocyte antigen-DR isotype (HLA-DR), as well as by the lack of expression of markers distinctive of mature lymphoid cells, such as CD3, CD19, and CD56\[^{31}\]. Typically, flow cytometry is performed to isolate MDSCs from peripheral mononuclear blood cells (PBMCs)\[^{29}\]. Fluorescent-labeled monoclonal antibodies are used to distinguish M-MDSCs and granulocytic MDSCs (G-MDSCs). M-MDSCs are identified as CD11b\(^+\)CD14\(^{hi}\)HLA-DR\(^{hi}\) and CD66b\(^-\), whereas G-MDSCs are recognized as CD11b\(^-\)CD14 CD33\(^+\)HLA-DR CD66b\(^+\). MDSCs can be distinguished from other immune suppressor cells within the myeloid lineage, \textit{e.g.}, tumor-associated macrophages and macrophage type 2, by other specific surface markers, including CD163 and F4/80\[^{29}\].

### Table 1 Two main categories of myeloid-derived suppressor cells and their immunosuppressive functions\[^{14}\]

| Type of MDSC      | Markers in humans | Immunosuppression mediator | Mechanism of immunosuppression                  |
|-------------------|-------------------|----------------------------|------------------------------------------------|
| PMN-MDSCs         | CD11b\(^+\)CD14\(^+\)CD15\(^+\)HLADR\(^{hi}\) or CD11b\(^+\)CD14\(^+\)CD66b\(^-\) or LOX-1\(^-\) | ARG1, ROS | Suppressing immune responses mainly in an antigen-specific manner; ROS production |
| M-MDSCs           | CD11b\(^-\)CD14\(^+\)CD15\(^+\)HLADR\(^{low/−}\) | NO, ARG1, and cytokines such as TGF-β and IL-10 | Suppressing T cell responses, both in antigen-specific and non-specific manners; production of NO and cytokines |

ARG1: Arginase 1; IL-10: Interleukin-10; M-MDSCs: Monocyctic myeloid-derived suppressor cells; NO: Nitric oxide; PMN-MDSCs: Polymorphonuclear myeloid-derived suppressor cells; ROS: Reactive oxygen species; TGF-β: Transforming growth factor-beta; MDSC: Myeloid-derived suppressor cell.
Figure 1 Chronic inflammation activates myeloid-derived suppressor cell generation, migration, and immunosuppression in the tumor microenvironment. Several cytokines and stimulator factors secreted by stroma and tumor cells (e.g., VEGF, granulocyte-macrophage colony-stimulating factor, IL-1, IL-6, HIF-1α, TGF-β, COX-2) trigger myeloid-derived suppressor cell (MDSC) generation and migration. Cytokines (e.g., CCL2, CCL3, CCL4, CCL5, CXCL1) stimulate the migration of MDSCs into the tumor microenvironment. At the tumor site, MDSCs undergo activation (via TNF, IL-10, IL-1, IL-6, IFN-γ, COX-2, HIF-1α, etc.) and suppress the anti-tumor reactivity of T and natural killer cells. Cross-talk between MDSCs and dendritic cells (DCs) impairs DC function and promotes tumor progression\[81\].

**MDSCs IN GI MALIGNANCIES**

**Esophageal cancer**

High levels of circulating MDSCs in esophageal cancer are associated with a poor prognosis\[5\]. Elevated MDSCs in the blood are correlated with elevated numbers of immunosuppressive cells, including Tregs\[5\]. Jiao et al\[36\] evaluated 31 esophageal cancer patients and 26 healthy controls (HCs), and found that MDSC numbers in the peripheral blood were increased 15-fold in esophageal cancer patients compared to HCs. The authors also showed that the plasma levels of ARG1 were 3-fold higher in cancer patients than in HCs. Xu et al\[37\] showed that 178 patients with esophageal cancer had a high level of G-MDSCs (> 82.5%), which were correlated with high morbidity due to the development of sepsis postoperatively after esophageal cancer surgery. The authors suggested that the level of G-MDSCs may be used to determine the incidence of sepsis in preoperative esophageal cancer patients postoperatively, and could improve the mortality of cancer-associated sepsis by targeting the level of MDSCs.

Additionally, a study by Chen et al\[38\] found that the levels of IL-6 and MDSCs predicted the prognosis and treatment response in mice with esophageal squamous cell carcinoma (SCC). The levels of MDSCs induced by IL-6 were linked to tumor growth and a poor prognosis. The authors concluded that targeted therapy against IL-6 with rapamycin or casein kinase 2 inhibitors might be a potential treatment modality for esophageal SCC\[38,39\].

**GC**

According to the Global Cancer Observatory (GLOBOCAN) 2018 database, GC is the fifth most common cancer and third most deadly cancer worldwide, with an estimated
783000 deaths in 2018. Li et al documented the levels of MDSCs in the peripheral blood of 21 GC patients who had not previously received treatment, and noted that the levels of MDSCs in these patients were about 4-fold higher than in the control groups. The authors concluded that cancer cell differentiation and lymph node metastasis are mostly related to the presence of M-MDSCs. They also showed that treatment with epirubicin and paclitaxel regimens can reduce the level of MDSCs in these patients, potentially leading to better outcomes for patients due to inhibition of cancer progression. Moreover, in 29 patients with GC and 18 HCs, MDSCs were increased in stage IV patients compared with HCs, and the 2-year survival rate of patients with higher levels of MDSCs was significantly poorer (median OS: 498 d vs 473 d; \( P = 0.048 \)), but no significant difference was observed in survival among patients with stage I, II, and III GCs. Previously, we reported that schlafen (SLFN) 4-expressing myeloid cells recruited to the stomach during Helicobacter infection undergo a phenotypic shift to G-MDSCs under the influence of damage-associated molecular pattern (DAMP) signaling and the production of IFN-\( \alpha \)/\( \beta \). SLFN4 is a myeloid cell differentiation factor that controls myelopoiesis. These SLFN-expressing MDSCs secrete factors including microRNAs, which can be detected in the peripheral blood as a biomarker and promote epithelial cell growth. This sustained immune dysregulation creates a microenvironment capable of supporting GC development.

**HCC**

HCC is a leading cause of death in cirrhotic patients. Per the GLOBOCAN 2018 database, 841000 new cases of primary liver cancer and 782000 deaths due to HCC occurred that year. In a prospective case-control study, Elwan et al demonstrated a higher number of MDSCs in the peripheral blood of cirrhotic groups without HCC than in patients with cirrhosis and HCC compared to patients in control groups. They showed that mean MDSC counts in the peripheral blood of cirrhotics without HCC group and cirrhotics with HCC group were about 3.5-fold and 5-fold higher compared to the control groups, respectively. Although not statistically significant, the authors reported a low number of MDSCs in the ascitic fluid of patients with both cirrhosis and HCC. Additionally, they investigated the correlation of levels of IFN-\( \gamma \) and alpha-fetoprotein with MDSC level. Their data showed that alpha-fetoprotein was positively and INF-\( \gamma \) was negatively correlated with MDSC count in the HCC group. A high frequency of MDSCs in the PBMCs of patients with HCC has been linked to more aggressive forms of HCC and poor clinical outcomes following local ablation, hepatectomy, or hepatic arterial infusion chemotherapy. A cohort study by Bayik et al showed an upsurge in circulating MDSC frequency in 114 patients with a secondary liver cancer, including CRC with liver metastases and neuroendocrine tumors, compared to individuals with benign lesions.

Data from animal models have shown that myeloid cells secrete MMPs, serine proteases, and cysteine cathepsins, which facilitate tumor cell invasion and metastasis by disrupting cell adhesion. Tumor angiogenesis in HCC can be promoted by MDSCs by producing high levels of MMP-9 in HCC.

**Pancreatic cancer**

The incidence of pancreatic ductal adenocarcinoma has significantly increased worldwide over the last 30 years, with a 5-year survival time less than 8%. Khaled et al demonstrated that G-MDSCs, but not M-MDSCs, are much higher in circulation and in the tumor tissue of patients with pancreatic cancer compared to HCs or those with chronic pancreatitis. These results suggest that the high level of G-MDSCs in pancreatic cancer plays a key factor in tumor development and progression. A cohort study reported that the percentages of all subpopulations of MDSCs were higher in patients with intraductal papillary mucinous neoplasm (IPMN) than in HCs, and were even higher in those with pancreatic adenocarcinoma. Although there was a trend towards higher MDSC levels in pancreatic cancer vs IPMN, it was not statistically significant (\( P = 0.33 \)).

**CRC**

A recent study reported that CRC cells induce an increase in the number of MDSCs by producing inflammatory factors, such as transforming growth factor-beta, IL-10, and ARG1. Consequently, T cell proliferation can be suppressed by tumor-derived MDSCs and promote tumor cell growth via oxidative metabolism. Previously, it was shown that the numbers of circulating Tregs and MDSCs are significantly reduced following tumor resection in patients with CRC. These data indicate that immunosuppression can be mitigated by reducing the number of MDSCs and Tregs in...
Farshidpour M et al. MDSC in gastrointestinal cancers

patients with CRC after reducing the tumor burden\cite{60}. Tada et al\cite{60} showed that patients with unresectable metastatic CRC with high M-MDSC, low CD4+ or low CD8+ effector memory T cell levels had significantly shorter progression-free survival.

**MDSC-TARGETED THERAPY**

Many studies have examined MDSCs as the core of targeted therapeutic strategies to improve tumor control in experimental animal models. These targeted therapies could be achieved by reducing MDSC numbers, hindering their trafficking and migration, or inhibiting their immunosuppressive function (Table 2)\cite{65}.

Because of variances in immunophenotype and mechanisms of suppression in the TME and diverse nature of human MDSCs, it is challenging to target human MDSCs\cite{60}. Wang et al\cite{60} treated pancreatic cancer patients with cytokine-induced killer (CIK) cell immunotherapy, CIK plus gemcitabine, and 5-fluorouracil (5-FU), and analyzed the levels of MDSCs in the peripheral blood pre- and post-treatment. The OS of metastatic pancreatic patients was increased with the combination of CIK and chemotherapy (gemcitabine and 5-FU) compared to patients treated with only CIK. Also, Jiang et al\cite{60} reported that the quality of life and 2-year survival rate improved in patients with advanced GC following combining chemotherapy (5-FU and oxaliplatin) with CIK cell treatment compared to treatment with chemotherapy alone. Tadalafil, the Federal Drug Administration-approved phosphodiesterase-5 inhibitor, can suppress MDSCs through downregulation of ARG1 and iNOS activities in several preclinical models\cite{63-65}. The authors also showed that the number of MDSCs was significantly reduced from 53.9% in phosphate-buffered saline-treated mice to 39% in sunitinib-treated mice. Sunitinib has established efficacy against advanced GI stromal tumors\cite{65}.

Treatment of esophageal SCC with 1α,25-dihydroxyvitamin D3 (calcitriol) has been shown to inhibit MDSC proliferation induced by IL-6 stimulation in C57 mice. Therefore, it has been proposed that this treatment may be a promising strategy for the prevention and treatment of esophageal SCC\cite{65}.

ICIs such as cytotoxic T-lymphocyte-associated protein 4 (ipilimumab and tremelimumab), PD-1 (pembrolizumab and nivolumab), and PD-L1 (atezolizumab, avelumab, and durvalumab) are promising treatment strategies that can be applied across numerous solid tumors\cite{66-68}. Pembrolizumab is a therapeutic antibody that blocks PD-1, and has shown promising anti-tumor activity in advanced GC\cite{67}. Although ICIs show great therapeutic benefits, substantial GI side effects such as colitis and GI bleeding can limit their use\cite{68}. However, due to immunosuppression, which is regulated by MDSCs, some patients with cancer may develop resistance to ICIs\cite{68}. Therefore, it is important to inhibit MDSC proliferation and migration to the TME by different strategies, such as anti-CXCR2 monoclonal antibody, to enhance PD-1 efficacy\cite{69}.

**CORONAVIRUS-19 AND MDSCS**

In this age of coronavirus-19 (COVID-19), we would be remiss not to address what is currently known about activation of the host’s immune response, in particular MDSCs, by severe acute respiratory syndrome-coronavirus-2 (SARS-CoV-2). Plasmacytoid DCs (pDCs) are the major source of tissue-derived type 1 IFNs in response to tissue antigens and activation of DAMPs. Typically, intracellular Toll-like receptors (TLRs) found on endosomes that mediate this pathway evolve to defend the cell against viral antigens and activation of DAMPs. Typically, intracellular Toll-like receptors (TLRs) (pDCs) are the major source of tissue-derived type 1 IFNs in response to tissue infection might correlate with the activation of endosomal TLRs on pDCs in the GI tract and increased myeloid cell polarization to MDSCs. If this occurs, the cellular immune response to the virus could be rendered ineffective, suggesting that those with severe disease exhibit higher levels of MDSCs than those with mild disease. Indeed, the limited studies available of COVID-19 patients have shown that the MDSC population expands in those with severe disease\cite{72,77}. Although T cell exhaustion from
Table 2 Potential therapeutic strategy for targeting myeloid-derived suppressor cells

| Strategy                                                                 | Agents                                                                 |
|-------------------------------------------------------------------------|------------------------------------------------------------------------|
| Blocking TDFs from being produced or from reaching the bone marrow      | Targeting the IL-6 receptor (tocilizumab) [{6, 8}^{14}]                |
| Key cytokines, such as IL-6 or S100A8/A9, could be directly targeted[{6, 8}^{14}] |                                                                        |
| Inhibiting generation of MDSCs from bone marrow progenitors or inducing apoptosis of circulating MDSCs [{8}^{14}] | Gemcitabine, 5-fluorouracil, sunitinib, and zoledronate [{8}^{14}] |
| Preventing trafficking of myeloid cells from the marrow to peripheral lymphoid organs or to the tumor microenvironment [{14}] | Drugs targeting chemokines CXCR2, CXCR4, and CSF1R [{8}^{14}] |

MDSCs: Myeloid-derived suppressor cells; CSF1R: Colony-stimulating factor 1 receptor; CXCR2: C-X-C motif receptor 2; CXCR4: C-X-C motif receptor 4; IL-6: Interleukin-6; TDFs: Tumor-derived factors.

CONCLUSION

This review article provides a better understanding of the role and mechanism of action of MDSCs in GI malignancies. MDSCs are one of the most important elements in the TME. In patients with GI cancer, MDSCs can lead to immunosuppression, and they play an important role in premalignant cell transformation, tumor growth, and metastasis. A higher number of MDSCs at tumor sites and peripheral blood is correlated with higher mortality rates, risk of relapse, and tumor progression. Therefore, monitoring circulating MDSC levels might have prognostic and predictive value in patients with GI malignancies. The benefit of targeting treatment against MDSCs as a combination therapy has been shown. Consequently, a better comprehension of the role and mechanism of action of MDSCs in the TME may aid in the development of novel immune-targeted therapies. Further prospective studies are needed to understand the characterization and clinical value of MDSCs and more selective anti-MDSC therapies with improved therapeutic outcomes.
