Abstract. We present in this paper a general model for determining the quantum properties of the light generated by a synchronously pumped optical parametric oscillator (SPOPÔ) operating below threshold. This model considers time and frequency on an equal footing, which allows us to find new quantum properties, related for example to the carrier envelope offset (CEO) phase, and to consider situations that are close to real experiments. We show that, in addition to multimode squeezing in the so-called 'supermodes', the system exhibits quadrature entanglement between frequency combs of opposite CEO phases. We have also determined the quantum properties of the individual pulses and their quantum correlations with the neighboring pulses. Finally, we determine the quantum Cramer–Rao limit for an ultra-short time delay measurement using a given number of pulses generated by the SPOPO.

1. Introduction

$\chi^{(2)}$ nonlinear media are efficient generators of non-classical states of light, such as squeezed states or quadrature entangled states, which are valuable resources for quantum metrology and quantum information processing in the continuous-variable regime [1, 2]. These non-classical states of light are produced by parametric down conversion (PDC) either in the single-pass regime [3] or inside a resonant cavity [4]. In the latter case, bright light is generated above some pump threshold value: one has an optical parametric oscillator (OPO). Due to the resonant cavity buildup, OPOs produce non-classical states of light with the moderate pump power delivered by continuous wave (cw) lasers. The quantum properties of cw OPOs have been extensively investigated over the last few years, both theoretically and experimentally. In the non-degenerate case, they produce below and above threshold EPR-entangled states of light [5–7]. In the degenerate case they produce below-threshold highly squeezed light in the resonant frequency and spatial modes which are resonant with the cavity [8, 9].

Recently, there has been rising interest in OPOs pumped by trains of ultra-short pulses, because of their promising properties: firstly, with such pumps, the efficiency of the nonlinear process can be increased further and the oscillation threshold lowered; secondly, the fact that the system generates light which spans over thousands of equally spaced frequency modes (‘frequency combs’) opens up the way to the efficient generation of highly multimode non-classical light [10–12]; in addition, such sources can be used for the quantum metrology of ultra-short time delays [13].

Synchronously pumped OPOs (SPOPOs) are OPOs for which the cavity round trip time is synchronized with the time interval between the pump pulses in order to favor the resonant cavity buildup. Such SPOPOs have been essentially developed as efficient classical sources of tunable ultra-short pulses [14–18] in the femtosecond regime. They have also been used to generate squeezed light in the picosecond regime [19] and more recently to produce multimode squeezed light in the femtosecond regime [20].
Previous theoretical works on the quantum properties of SPOPOS below threshold [12, 21, 22] have shown that SPOPOS generate multimode squeezed frequency combs and that there exist quantum correlations between pulses in different time intervals. These investigations have been carried out either totally in the frequency domain (longitudinal modes), or totally in the time domain. In this paper, we use the quantum input–output approach and develop a formalism which allows us to treat the quantum properties of the SPOPO in the frequency and the time domain on an equal footing. This enables us to find new interesting properties, related in particular to the carrier envelope offset (CEO) phase, and to present a comprehensive model, capable of taking into account more realistic conditions, such as the intra-cavity dispersion [23].

The paper is organized as follows. In section 2, we first present an input–output formalism for treating OPOs in the general case. Then, in section 3, we treat the case of an OPO pumped by a train of synchronous pulses and derive the quantum properties of the field that is generated below threshold. In section 4, the quantum properties of individual pulses are derived. Finally, we evaluate in section 5 the quantum improvement of the estimation of ultra-short time delays using the pulses generated by the SPOPO. Appendices give more technical details of the derivation of some of the results presented.

2. Input–output relation for lossless degenerate ring-cavity optical parametric oscillators below threshold

Let us consider an OPO in a ring-cavity configuration, where the cavity is transparent for the pump, and a $\chi^{(2)}$ crystal in degenerate type-I configuration is placed in the cavity (see figure 1).

M1 is the output coupler and D represents the group of linear passive devices inserted for dispersion compensation. We will ignore the transverse spatial dependence for the sake of simplicity. In the free space outside the cavity, the positive-frequency components of the incoming and outgoing quantum fields can be written, within the slowly varying envelope approximation, as [24]

$$\hat{E}^{(+)}_{\sigma}(t) = i \hat{E}_{\sigma}(t) e^{-i \omega_0 t}, \quad \text{with } \sigma = \text{in, out},$$  

where $\hat{E}_{\sigma}$ is the single-photon electric field, $\omega_0$ is the carrier frequency of both fields and $\hat{a}_{\text{in}}$ and $\hat{a}_{\text{out}}$ are the slowly varying annihilation operators that verify the commutation relations

$$[\hat{a}_{\sigma}(t), \hat{a}_{\sigma}(t')] = 0 \quad \text{and} \quad [\hat{a}_{\sigma}(t), \hat{a}_{\sigma}^\dagger(t')] = \delta(t-t').$$  

Figure 1. Sketch of the SPOPO ring cavity.
One can also write the positive electric field operator in terms of annihilation operators of frequency modes, which are the Fourier transforms of time-dependent annihilation operators and defined as \( \hat{a}_\sigma(\omega) = \int_0^\infty \hat{a}(t) e^{-i\omega t} \, dt \), so that
\[
[\hat{a}_\sigma(\omega), \hat{a}_\sigma^\dagger(\omega')] = 2\pi \delta(\omega - \omega').
\] (3)

Also for the sake of simplifying the model we assume that the losses are negligible. Thus, since the pump depletion is negligible below threshold, the OPO that we are dealing with is a linear lossless system, where the outgoing (output) field only explicitly depends on the incoming (input) field. Hence, the most general relation for our system reads, in the time as well as in the frequency domain,
\[
\begin{pmatrix}
\hat{a}_{\text{out}} \\
\hat{a}_{\text{out}}^\dagger
\end{pmatrix}
= \mathcal{R}
\begin{pmatrix}
\hat{a}_{\text{in}} \\
\hat{a}_{\text{in}}^\dagger
\end{pmatrix},
\text{ with } \mathcal{R} = \begin{pmatrix}
\mathcal{C} & \mathcal{S} \\
\mathcal{S}^* & \mathcal{C}^*
\end{pmatrix},
\] (4)

where \( \mathcal{C} \) and \( \mathcal{S} \) are integral transforms. For example, \( \mathcal{C}\hat{a}_{\text{in}} \) reads \( \int_0^\infty \mathcal{C}(t, t')\hat{a}_{\text{in}}(t') \, dt' \) in the time domain and \( \int_0^\infty \mathcal{C}(\omega, \omega')\hat{a}_{\text{in}}(\omega') \, d\omega' \) in the frequency domain, where \( \mathcal{C} \) is the integral kernel. Since relation (4) must preserve commutation relations (2), the above linear Bogoliubov transform should be complex symplectic (hereinafter, simply called symplectic), equivalent to a \( 2 \times 2 \) real symplectic transform [25]. The necessary and sufficient condition for this is
\[
\mathcal{R}^{-1} = \sigma_1 \mathcal{R}^* \sigma_1, \quad \text{with } \sigma_1 = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}.
\] (5)

Note that the effect of linear losses or other cavity configurations can also be described by using a symplectic transform, where the dimension of the system is increased while the symplectic character of the transformation is preserved.

For our linear and lossless system, the expression of \( \mathcal{R} \) can be found with the help of the relations between classical fields [8]. We denote by \( \mathcal{T}_{\text{RT}} \) the cavity round-trip transform, which relates the internal field envelopes after and before the output coupler M1, i.e.
\[
\begin{pmatrix}
A_1 \\
A_1^*
\end{pmatrix}
= \mathcal{T}_{\text{RT}} \begin{pmatrix}
A_2 \\
A_2^*
\end{pmatrix},
\] (6)

where \( A_{1,2}(t) = E_{1,2}^{(s)}(t) \exp(i \omega_0 t) \) are the slowly varying envelopes. Since (6) also holds without the output coupler M1, \( \mathcal{T}_{\text{RT}} \) is symplectic. We can write
\[
\mathcal{T}_{\text{RT}} = \mathcal{U}_{1B} \mathcal{S}_{BA} \mathcal{U}_{A1},
\] (7)

where \( \mathcal{S}_{BA} \) is the transform of the \( \chi^{(2)} \) crystal, and \( \mathcal{U}_{A1} \) and \( \mathcal{U}_{1B} \) are transforms from M1 to point A and from B to M1. These transforms must all be symplectic, and their explicit expressions will be discussed later. At M1, the boundary condition for lossless coupling of the internal and external fields can be written as
\[
\begin{pmatrix}
E_1 \\
E_{\text{out}}
\end{pmatrix}
= \begin{pmatrix} t & r \\ -r & t \end{pmatrix}
\begin{pmatrix}
E_{\text{in}} \\
E_2
\end{pmatrix},
\] (8)

2 In this paper, bold letters will denote the matrix and vectors, and calligraphic letters will denote integral transforms. The underline will denote either the Fourier transforms, defined as: \( \underline{\alpha}(\omega) = \int_0^\infty \alpha(t) e^{-i\omega t} \, dt \), or the kernels in the frequency domain.
where \( t \) and \( r \) are real amplitude transmission and reflection coefficients \((r^2 + t^2 = 1)\), which are assumed to be constant in the frequency range of interest. Then, with (6) and (8), we find that

\[
\mathcal{R} = \frac{T_{RT} - r}{1 - r T_{RT}} = r^{-1} \left( \frac{t^2}{1 - r T_{RT}} - 1 \right),
\]

which, formally independent of the pumping condition, can be considered as a generalization of previous works (see, for example, equation (5.13b) of [26]). From (9), it is easy to verify that \( \mathcal{R}(T_{RT}) = \mathcal{R}^{-1}(T_{RT}^{-1}) \). Then, since \( T_{RT} \) is symplectic, one can show with (5) that \( \mathcal{R} \) is symplectic.

Outside the crystal, the transforms \( \mathcal{U}_{A1} \) and \( \mathcal{U}_{1B} \), which are defined in (7), describe the lossless linear dispersive propagations. They are unitary diagonal, for example, \( \mathcal{U}_{A1} = \text{Diag}(\mathcal{U}_{A1}, \mathcal{U}_{A1}') \), where \( \mathcal{U}_{A1} \) is unitary and its kernel reads

\[
\mathcal{U}_{A1}(\omega, \omega') = \delta(\omega - \omega') \exp[i \phi_{A1}(\omega)],
\]

\( \phi_{A1}(\omega) \) being the spectral phase modification due to the propagation from M1 to A.

In the lossless crystal, which extends from \( z_A = -l_c/2 \) to \( z_B = l_c/2 \), with the non-depleted pump approximation, the signal propagation can be described by the linear evolution of its slowly varying envelope: \((A_s(z), A_s^*(z))^T = S(z)(A_s(z_A), A_s^*(z_A))^T\). So, the transform describing the propagation in the \( \chi^{(2)} \)-crystal is given by \( S_{BA} = S(z_B) \). From the classical description of traveling-wave degenerate PDC \([11, 27] \), \( S(z) \) can be found by solving

\[
\partial_z S(z) = K(z) S(z), \quad S(z_A) = 1,
\]

with the kernel of \( K(z) \) given by

\[
K(z, t, t') = \begin{pmatrix}
-i k_s(-i\delta_t) & 2\pi \chi_0 A_p(z, t) \\
2\pi \chi_0 A_p^*(z, t) & i k_s(i\delta_t)
\end{pmatrix} \delta(t - t').
\]

(12)

In this relation, the diagonal part describes the free propagation in the lossless medium and \( k_s(-i\delta_t) \) is the signal wavevector \( k_s(\omega_0 + \omega) \) around \( \omega_0 \) in which \( \omega \) has been replaced by \(-i\delta_t\), whereas the anti-diagonal part describes the PDC process. Because \( \sigma_1 K^T(z) \sigma_1 = -K(z) \), we have \( \sigma_1 S^T(z) \sigma_1 S(z) = 1 \). Thus, from (4), we see that (11) and (12) describe a symplectic evolution.

The effective nonlinear coefficient \( \chi_0 \) is given by

\[
\chi_0 = \left( \frac{2\omega_p^2}{\epsilon_0 n_0^2 c^3 \omega_{\text{eff}}} \right)^{1/2} d_{\text{eff}},
\]

(13)

where \( n_0 = c k_s(\omega_0)/\omega_0 \) is the mean refractive index for the signal wave, \( \omega_{\text{eff}} \) is the effective area of degenerate three-wave mixing and \( d_{\text{eff}} \) is the effective nonlinearity coefficient for the given phase-matching configuration. The pump field envelope reads in the frequency domain: \( \bar{A}_p(z, \omega) = A_p(\omega) \exp[-i k_p(\omega) z] \), where \( k_p(\omega) \) is the pump wavenumber at optical frequency \( 2\omega_0 + \omega \). It is normalized so that \( |A_p(z, t)|^2 \) is the pump power.

For OPOs, as long as the cavity finesse is relatively high, the amount of round-trip PDC is generally small below threshold. So, an approximate symplectic solution of (11) and (12) can be adopted, which is in fact the first-order approximation of a Magnus expansion,
also known as exponential perturbation theory, that preserves the symplectic character of the transformation [28]:

$$S_{BA} = U_{BA} G_0,$$

where $U_{BA}$ is the crystal’s unitary transform without pumping, and

$$g_0 = \exp \left( \frac{0}{S_0^*} S_0 \right),$$

with

$$S_0(\omega, \omega') = \chi_{0l_c} A_p(\omega + \omega') \Phi(\omega, \omega'),$$

where $\Phi(\omega, \omega') = \sin\Delta\Phi(\omega, \omega')/\Delta\Phi(\omega, \omega')$ is the phase-matching function with $\Delta\Phi(\omega, \omega') = l_c[k_s(\omega) + k_s(\omega') - k_0(\omega + \omega')]/2$. Since $S_0$ is symmetric, $g_0$ is symplectic and positive-definite. Thus, from (7) and (14), we can write $T_{RT} = U_{RT} g_{RT}$, where $U_{RT} = U_{AB} U_{BA} U_{A1}$ is the round-trip unitary transform without pumping, and $g_{RT} = U_{A1}^* g_{AB} U_{A1}$ is the positive transform of round-trip parametric gain. In the following, we will replace $g_{RT}$ by $g_0$, which amounts to performing a unitary transform ($\hat{a}_\sigma \rightarrow U_{A1}\hat{a}_\sigma$) simultaneously on the input and the output. So, (9) can be rewritten as

$$\mathcal{R} = r^{-1} \left( \frac{t^2}{1 - r U_{RT} g_0} - 1 \right).$$

The round-trip unitary transform $U_{RT}$ describes the passive round-trip spectral phase modification, $\phi_{RT}(\omega)$. Around the signal carrier frequency $\omega_0$, it can be approximated as a polynomial of $\omega$. For the sake of simplicity, we will assume the higher-order dispersions are compensated or negligible so that

$$\phi_{RT}(\omega) = \Delta_{RT} + \omega T_0,$$

where $T_0$ is the round-trip time, and $\Delta_{RT}$ is the round-trip phase shift that detunes the resonance of cavity. Therefore, the kernel of $U_{RT}$ reads in the time domain

$$U_{RT}(t, t') = \delta(t - t' + T_0) e^{i\sigma_1 \Delta_{RT}},$$

which describes a time translation with a phase shift on the field envelope.

3. Frequency combs as a basis for analyzing synchronously pumped optical parametric oscillators (SPOPOs) quantum properties

We will now apply the general formalism of section 2 to the specific case of SPOPOs, in which the pump pulses are synchronized with the cavity, so that the pump field envelope can be written as

$$A_p(t) = \sqrt{\varepsilon_p} \sum_k e^{2i\Delta_0} \alpha_p(t - k T_0),$$

where $\varepsilon_p$ is the pump pulse energy, $2\Delta_0$ is the pump CEO and $\alpha_p(t)$ is the pulse envelope function, non-zero on $[0, T_0]$ and normalized, such that $\int_{[0]} |\alpha_p(t)|^2 dt = 1$. Since the pump field is quasi-$T_0$-periodic: $A_p(t + k T_0) = A_p(t) e^{2ik\Delta_0}$, we have a quasi-periodic system. From (11) and (12), we see that the kernels of $S_{BA}$, $g_0$ and $S_0$ are quasi-periodic translation invariant, e.g.

$$g_0(t + T_0, t' + T_0) = e^{i\sigma_1 \Delta_0} g_0(t, t') e^{-i\sigma_1 \Delta_0}.$$
With (20), we can rewrite (16) in the time domain as

\[ S_0(t, t') = \sum_k S_c(t - kT_0, t' - kT_0) e^{2\pi \Delta_0}, \tag{22} \]

where the kernel of \( S_c \) reads in the frequency domain

\[ S_c(\omega, \omega') = \chi_0 p \Phi^{1/2}_p (\omega + \omega') \Phi (\omega, \omega'). \tag{23} \]

In what follows, we will assume that

\[ S_c(t, t') = 0, \quad \forall t, t' \notin T_0, \tag{24} \]

the validity of which requires that the spectral width of the phase-matching function \( \Phi (\omega, \omega') \) is much larger than the repetition rate \( T_0^{-1} \) and that the pump pulses are localized around the center of each period and have a temporal width much smaller than \( T_0 \). These conditions are generally satisfied in practice with SPOPOs ultra-short pulses. Physically, (24) implies that the signal photons down-converted from the pump photons in each period will not travel into other periods when leaving the crystal.

Due to the quasi-periodicity property (21), \( \mathcal{G}_0 \) commutes with a unitary pseudo-time translation \( \mathcal{U}_0 \) whose kernel reads

\[ \mathcal{U}_0(t, t') = \delta(t - t' + T_0) e^{-i \sigma_1 \Delta_0} = e^{-i \sigma_1 (\Delta_{RT} + \Delta_0)}, \tag{25} \]

where the second line comes from (19). So, \( \mathcal{G}_0 \) and \( \mathcal{U}_0 \) have common eigenvector functions. The eigenvalue problem of these two transforms is discussed in appendix A. With condition (24), we have

\[ \mathcal{G}_0 f_n^{(\pm)} (\theta) = e^{\pm g_n} f_n^{(\pm)} (\theta), \tag{26} \]

\[ \mathcal{U}_0 f_n^{(\pm)} (\theta) = e^{i \theta} f_n^{(\pm)} (\theta), \tag{27} \]

with \( g_n \geq 0, \theta \in [-\pi, \pi] \) and

\[ f_n^{(\pm)} (\theta, t) = \frac{1}{\sqrt{2}} \begin{pmatrix} f_n (\theta, t) \\ \pm f_n^* (-\theta, t) \end{pmatrix}. \tag{28} \]

In the above expression, \( f_n (\theta, t) \) is the eigenfunction of \( S_0 S_0^\dagger \) and reads

\[ f_n (\theta, t) = \frac{1}{\sqrt{2\pi}} \sum_{k=-\infty}^{+\infty} \psi_n (t - kT_0) e^{i k (\theta + \Delta_0)}, \tag{29} \]

with \( \psi_n (t) = 0, \forall t \notin T_0, \) where \( \psi_n (t) \) is the eigenfunction of \( S_c S_c^\dagger \) with eigenvalue \( g_n^2 \). The set \( \{\psi_n\} \) is orthonormal and complete over \( T_0 \).

We see that each function \( f_n (\theta, t) \) represents a continuous train of pulses, with a CEO of \( \theta + \Delta_0 \). In the frequency domain, as shown in figure 2, \( f_n (\theta, \omega) \) is a frequency comb shifted by \( \theta T_0^{-1} \) from the central frequencies of PDC \( (2n\pi + \Delta_0) / T_0 \). The envelope functions \( \{\psi_n\} \) are the so-called supermodes [21] and have also been studied in the context of single-pass and single-pump pulse [10, 11], i.e. \( T_0 \to \infty \). One contribution of this paper is the introduction of the parameter of frequency shift, \( \theta \), that is proper for describing frequency combs. In appendix B,
we show that \( \{ f_n(\theta, t) \} \) forms a complete orthonormal set over the real time axis. So, the slowly varying envelope operators can be decomposed on the basis of frequency combs:

\[
\hat{a}(t) = \sum_n \int_{-\pi}^{+\pi} \hat{a}_n(\theta) f_n(\theta, t) \, d\theta,
\]

where \( \hat{a}_n(\theta) = \int_{-\infty}^{+\infty} f_n^*(\theta, t) \hat{a}(t) \, dt \) is the frequency comb annihilation operator whose commutation relations read \([\hat{a}_n(\theta), \hat{a}_m(\theta')] = 0\) and \([\hat{a}_n(\theta), \hat{a}_m^\dagger(\theta')] = \delta_{nm} \delta(\theta - \theta')\).

Now, on the basis of frequency combs, with (25), (26), we are ready to perform a Bloch–Messiah reduction [29] on the transform (17). This yields

\[
\begin{pmatrix}
\hat{a}_{\text{out}, n}(\theta) \\
\hat{a}_{\text{out}, n}^\dagger(-\theta)
\end{pmatrix} = e^{i\theta T_n - r} \frac{1}{1 - re^{i\theta T_n}} \begin{pmatrix}
\hat{a}_{\text{in}, n}(\theta) \\
\hat{a}_{\text{in}, n}^\dagger(-\theta)
\end{pmatrix},
\]

with

\[
T_n = e^{i\sigma_1(\Delta_T + \Delta_0)} \begin{pmatrix}
\cosh g_n & \sinh g_n \\
\sinh g_n & \cosh g_n
\end{pmatrix}.
\]

We can rewrite (31) in the form

\[
\hat{a}_{\text{out}, n}(\theta) = C_n(\theta) \hat{a}_{\text{in}, n}(\theta) + S_n(\theta) \hat{a}_{\text{in}, n}^\dagger(-\theta)
\]

with \(|C_n(0)|^2 - |S_n(0)|^2 = 1\). Thus the input–output relation (33) describes a squeezing transformation if \( \theta = 0 \) and twin photon generation when \( \theta \neq 0 \). We conclude that SPOPOs are multimode squeezers for frequency combs with zero-frequency shift from the central frequencies of PDC. In the time domain, these frequency combs are continuous trains of pulses with a CEO half that of the pump. For \( \theta \neq 0 \), SPOPOs generate pairs of entangled frequency combs with opposite frequency shifts or in the time domain continuous trains of pulses whose CEOs are symmetric with respect to \( \Delta_0 \), i.e. \( \Delta_0 = \theta \). This is just as in the cw case where the cw modes with optical frequencies \( \omega_0 \pm \omega \) are entangled. These entangled pairs are in the so-called two-mode squeezed state, and each part alone of an entangled pair is in a thermal state [30]. This implies that, when detecting the squeezing of SPOPOs in a homodyne detection scheme, the local oscillator should be either a frequency comb with zero-frequency shift or a combination of frequency comb pairs with opposite frequency shifts.

From (30), we see that the resonant cavity enhances the squeezing effect in a frequency range having a width close to the cavity bandwidth. In practice, to obtain maximum squeezing the round-trip phase shift \( \Delta_T \) of the cavity should be adjusted so that \( \Delta_T + \Delta_0 \) approaches a multiple of \( \pi \). As can be seen from (31), the threshold of SPOPOs corresponds to the singular...

**Figure 2.** Spectrum of a frequency-shifted frequency comb.
point of the input–output transform. Let us assume that \( r > 0 \). Then, we find that the threshold of SPOPO is reached as

\[
g_0 = \max(g_n) \rightarrow a \cosh \left( \frac{1 + r^2}{2r \cos(\Delta_{RT} + \Delta_0)} \right)
\]

(34)

for \( \theta = 0 \) if there exists an integer \( n \) such that \(|\Delta_{RT} + \Delta_0 - 2n\pi| < \pi/2\), or at \( \theta = \pi \) when \(|\Delta_{RT} + \Delta_0 - (2n+1)\pi| < \pi/2\). This corresponds to the two regimes of the degenerate OPO above threshold [18].

4. Quantum properties of individual pulses

Now, let us consider individual pulses. We define the annihilation operator for the pulse in the \( n \)th supermode and on the \( k \)th period, \( \hat{a}_k \), as

\[
\hat{a}_n,k = \int_{\mathcal{J}_k} \psi^*_n(t - kT_R) \hat{a}(t) \, dt
\]

\[
= \frac{1}{\sqrt{2\pi}} \int_{-\pi}^{\pi} e^{ik\theta} \hat{a}_n(\theta) \, d\theta,
\]

(35)

whose non-zero commutation relation is \([\hat{a}_{n,k}, \hat{a}^\dagger_{m,k'}] = \delta_{nm}\delta_{kk'}\). To obtain the second line of (35), we have used (29) and (30). Inversely, one has

\[
\hat{a}(t) = \sum_{n,k} \hat{a}_{n,k} \psi_n(t - kT_R).
\]

(36)

The Hermitian quadrature operators are defined as usual by \( \hat{x}_{n,k} = (\hat{a}_{n,k} + \hat{a}^\dagger_{n,k})/\sqrt{2} \) and \( \hat{p}_{n,k} = i(\hat{a}_{n,k} - \hat{a}^\dagger_{n,k})/\sqrt{2} \), with \([\hat{x}_{n,j}, \hat{p}_{m,k}] = i\delta_{nm}\delta_{kk'}\). From (31), (32) and (35), and assuming \( \Delta_{RT} + \Delta_0 = 2n\pi \), we obtain another form of the input–output relation for SPOPOs:

\[
q^{(\pm)}_{n,k} = -r q^{(\pm)}_{0,n,k} + t^2 \sum_{s=1}^{\infty} t^{s-1} e^{\pm i\epsilon_s} q^{(\pm)}_{0,n,k-s},
\]

(37)

where \( \hat{q}^{(+)\dagger}_{n,k} = \hat{x}_{n,k} \) and \( \hat{q}^{(-)\dagger}_{n,k} = \hat{p}_{n,k} \). If \( \Delta_{RT} + \Delta_0 = (2n+1)\pi \), another expression can be obtained by replacing the reflection coefficient \( r \) in the above expression with \(-r\). From (37), we see that each output pulse can be considered as the combination of the direct reflection of a first pulse and of the transmission of the successive intra-cavity pulses related to pulses that previously entered the cavity.

In what follows, we will assume that the input is in a coherent state, including vacuum state. Thus, the output pulses are in a Gaussian state characterized by their variance matrix [25]. Using (37), the non-zero matrix elements can be found to be \( \langle \Delta q^{(\pm)}_{n,j} \Delta q^{(\pm)}_{n,k} \rangle = V^{(\pm)}_{n,(j,k)} \), with

\[
V^{(\pm)}_{n,(j,k)} = \frac{\delta_{j,k}}{2} \left( \frac{r^2}{1 - r^2} e^{\pm 2\epsilon_s} \right) - \frac{\overline{\delta}_{j,k}}{2} \frac{1 - e^{\pm 2\epsilon_s}}{1 - r^2} e^{\pm 2\epsilon_s}(r e^{\pm \epsilon_s})^{j-k},
\]

(38)

where \( \overline{\delta}_{j,k} = 1 - \delta_{j,k} \), the first term of the right-hand side is the quadrature variance and the second is the covariance.
Two conclusions can be drawn from this variance matrix. Firstly, each pulse is in a Gaussian state which is not a pure state: one can verify that $V_{n,(k,k)}^{(\pm)} V_{n,(k,k)}^{(-)} > 1/4$ as long as $g_n > 0$. At threshold, the squeezing of the $p$-quadrature of each pulse is limited, $V_{0,(k,k)}^{(-)} = 2r^2/(1 + r^2)$, whereas $V_{0,(k,k)}^{(\pm)} \to \infty$. Secondly, there are pulse-to-pulse quantum correlations and anti-correlations on, respectively, the $x$- and $p$-quadratures. As the time difference between the pulses increases, these correlations decrease, respectively, at a rate $re^{\pm g_n}$. It should be pointed out, however, that these quantum correlations are not strong enough to ensure bipartite entanglement between any two pulses. This can be verified on the Duan criterion with the variance matrix given by (38) [31].

Let us finally consider $N$ successive pulses that are in the $n$th supermode. As discussed above, these pulses are in a mixed Gaussian state described by the variance matrices of their quadratures $V_{n}^{\pm}(N)$. It will be useful to look at the minimum eigenvalue problem of the $p$-quadrature variance matrix:

$$V_{n}^{(-)}(N)c_{n,0}^{(N)} = \left[\sigma_{n,0}^{(-)}(N)\right]c_{n,0}^{(N)}, \quad (39)$$

where $[\sigma_{n,0}^{(-)}(N)]^2$ is the minimum eigenvalue, and $c_{n,0}^{(N)}$ the corresponding eigenvector. With the explicit expression (38), they can be found semi-analytically (see equation (1.353.3) in [32]). The normalized elements of $c_{n,0}^{(N)}$ read

$$c_{n,0}^{(N)}(k) = \mathcal{M}_{n,0}^{(N)} \cos\left[\frac{1}{2} \theta_{n,0}^{(N)} (N-2k-1)\right], \quad (40)$$

where $0 \leq k < N - 1$, $\mathcal{M}_{n,0}^{(N)}$ is a normalization coefficient, and $\theta_{n,0}^{(N)}$ can be found by solving

$$\frac{\cos \theta_{n,0}^{(N)} (N+1)}{\cos \theta_{n,0}^{(N)} (N-1)} = re^{-g_n}, \quad \text{with } 0 < N\theta_{n,0}^{(N)} < \pi. \quad (41)$$

The minimum variance is then

$$[\sigma_{n,0}^{(-)}(N)]^2 = \frac{1}{2} \left| \frac{r - e^{\theta_{n,0}^{(N)}} e^{-g_n}}{1 - re^{\theta_{n,0}^{(N)} e^{-g_n}}} \right|^2. \quad (42)$$

It is interesting to note that, at large $N$ where $\theta_{n,0}^{(N)} \to 0$, it becomes the variance of the $p$-quadrature of the squeezed frequency comb $\hat{a}_n(0)$, and strong squeezing is re-found as expected.

5. Quantum Cramer–Rao bound for time estimation using SPOPO pulses

SPOPOs deliver trains of pulses which can be used as a clock when the pump repetition rate is locked on a time standard, with which can be measured with a very high accuracy the exact time of occurrence of a given event. It is well known that quantum noise squeezing or quantum correlations can be used to improve the measurements of physical quantities. The question we address in this section is the determination of the minimum uncertainty that can be reached in the estimation of the temporal positioning of the train of pulses using the quantum properties of the light produced by SPOPOs, independently of the exact quantity measured and on the precise
protocol employed for extracting the estimator from the measured quantities: this minimum uncertainty is given by the quantum Cramer–Rao bound [33] that we will now calculate.

Let us consider a probe field which is time translated by a small quantity \( \tau \): \( \hat{a}(t) e^{i\omega_0 t} \rightarrow \hat{a}(t + \tau) e^{i\omega_0(t+\tau)} \), which can be considered as the result of a unitary transform

\[
\hat{U}(\tau) = \exp \tau \int_{-\infty}^{+\infty} \hat{a}^\dagger(t) (i\omega_0 + \hat{\eta}) \hat{a}(t) \, dt.
\]

We want to estimate the time delay, \( \tau \), using \( N \) successive SPOPO squeezed pulses on the time interval \([0, NT_0]\). Due to (36), the reduced system can be shown to evolve under a unitary transform. In the Schrödinger picture, this reads

\[
\hat{\rho}^{(N)}(\tau) = e^{i\Omega N \tau} \hat{\rho}^{(N)}(0) e^{-i\Omega N \tau},
\]

where \( \hat{\rho}^{(N)}(0) \) is the initial state of the \( N \) pulses, described by the variance matrix (38), and

\[
\hat{\Omega}_N = \sum_{k=0}^{N-1} \sum_{m,n} \Omega_{mn} \hat{a}^\dagger_{m,k} \hat{a}_{n,k},
\]

with \( \Omega_{mn} = \int \psi^*_m(t) (\omega_0 - i\hat{\eta}) \psi_n(t) \, dt \).

According to the quantum estimation theory, the estimation precision of the time delay is limited by the quantum Cramer–Rao bound, equal to the inverse of the quantum Fisher information \( F \) that depends only on the quantum state of the system used in the measurement, given by (44) in the present case. In appendix C, we show that, under the assumption that the probe field is intense and \( \tau \) is small, \( F \) can be approximately evaluated as

\[
F_N = \frac{1}{2} \sum_n (\vec{\alpha}'_n)^T \Lambda_n^{(-)}(N) \vec{\alpha}'_n,
\]

where \( \Lambda_n^{(-)}(N) = [V_n^{(-)}(N)]^{-1} \), and the vector elements of \( \vec{\alpha}'_n \) are defined by

\[
\alpha'_{n,k} = \sum_m \Omega_{n,m} \langle \hat{a}_{m,k} \rangle,
\]

which have been assumed to be real. In order to minimize the quantum Cramer–Rao bound with a fixed mean photon number in the probe field during the measurement time, the vectors \( \vec{\alpha}'_n \) should be proportional to \( \delta_n e^{\gamma(N)}_{0,0} \), where \( e^{\gamma(N)}_{0,0} \) is defined by (39). Then, with (47), we find the optimal probe photon field envelope, which reads

\[
\alpha^{(N)}(t) = \alpha^{(N)}_0 \sum_{k=0}^{N-1} c^{(N)}_{0,0}(k) \psi'_0(t - kT_R),
\]

where \( \psi'_0(t) \) is the probe-pulse envelope defined as

\[
(\omega_0 - i\hat{\eta}) \psi'_0(t) = \psi_0(t),
\]

and \( \alpha^{(N)}_0 = \sqrt{N\bar{n}_0(\omega_0^2 + \Delta\omega_0^2)} \), with \( N\bar{n}_0 = \int |\alpha^{(N)}(t)|^2 dt \) the total photon number of the mean probe field and \( \Delta\omega_0^2 \) its spectral spread [13]. Then, the optimal quantum Cramer–Rao bound
Figure 3. Quantum improvement of the estimation of a time delay, $\Delta \tau / \Delta \tau_{\text{SQL}}$, as a function of pulse number $N$. SPOPO cavity finesse: $F \approx 30$.

reads

$$\Delta \tau^2 = \frac{[\sigma_{0,0}^(-)(N)]^2}{2N\sigma_0^2 + \sigma_0^2} = 2\Delta \tau_{\text{SQL}}^2 \sigma_{0,0}^(-)^2, \quad (50)$$

where $\Delta \tau_{\text{SQL}}^2$ is the standard quantum limit using $N$ coherent pulses, as given in [13].

Figure 3 shows an example of the quantum improvement of time estimation, $\Delta \tau_{\text{SQL}} / \Delta \tau$, as a function of pulse number $N$ and for different levels of the distance to oscillation threshold. We see that this quantity is always larger than 1, as expected, and that the improvement increases with the number of pulses used in the measurement until it reaches a limit for large $N$ equal to $\sqrt{2}\sigma_{0,0}^(-)^{-1}(\infty)$ that is defined by (42). We can then know the minimum number of pulses, and therefore the minimum measurement time, needed to reach the limit. In addition, one can verify that the optimal quantum Cramer–Rao bound (50) is achievable with the optimal probe field (48) and the balanced homodyne detection described in [13], where the local oscillator is composed of $N$ equal intense coherent pulses in the supermode $\psi_0(t)$.

6. Conclusion

In conclusion, we have presented in this paper a novel time–frequency model for determining the quantum properties of OPOs below threshold based on a general input–output formalism that we have applied to the SPOPO case. The impact of the pump CEO and of the cavity round-trip phase on these properties has been studied. We have seen that the frequency combs, or continuous trains of pulses, form a natural basis for analyzing SPOPOs. As in the pulsed single-pass configurations, the squeezing of SPOPO is multimode and the number of effectively squeezed modes depends on the pump spectrum and the phase-matching condition. We have shown that SPOPOs generate pairs of entangled frequency combs with frequency shifts symmetric with respect to the central frequencies of PDC.

SPOPOs have also been analyzed in the regime of individual pulses. We have shown that each individual pulse is in a squeezed thermal state, and the two quadratures of the pulses are correlated and anti-correlated. The variance matrices of the quadratures have been analytically evaluated. Not surprisingly, due to these pulse-to-pulse correlations, strong squeezing is
re-found in the multipulse regime. Finally, we have discussed the optimization of quantum improvement of time estimation with a limited number of SPOPO squeezed pulses.

In this paper, we have applied the model to the simplest case of a lossless degenerate type-I ring cavity in the dispersion-compensated configuration, but it can serve as a framework for analyzing more complex configurations that are closer to real experimental conditions, such as higher-order intra-cavity dispersion effects or the influence of the transverse spatial dependence.

Appendix A

Here, we first show how to find the common eigenvector functions of $U_0 = \text{Diag}(U_0, U_0^*)$ defined in (25) and

$$H_0 = \ln G_0 = \begin{pmatrix} 0 & S_0 \\ S_0^* & 0 \end{pmatrix},$$

(A.1)

which is defined by (15). Since $U_0$ is unitary, its eigenvalues are complex and on the unit circle, i.e.

$$U_0 f(\theta) = e^{i\theta} f(\theta).$$

(A.2)

Writing $f(\theta) = (f_1(\theta), f_2^*(\theta))^T$, from (25), we have

$$f_1(\theta, t + T_0) = f_1(\theta, t) e^{i(\Delta_0 + \theta)},$$

$$f_2(\theta, t + T_0) = f_2(\theta, t) e^{i(\Delta_0 - \theta)},$$

(A.3)

which means that they are quasi-$T_0$-periodic functions. Let us assume that $f(\theta)$ is also the eigenvector of $H_0$, i.e. $H_0 f(\theta) = g(\theta) f(\theta)$, where the eigenvalue $g(\theta)$ is a real number because $H_0$ is Hermitian. From $\sigma_1 H_0 \sigma_1 = -H_0$, we see that $\sigma_1 f(\theta)$ is also the eigenvector of $H_0$ with eigenvalue $-g(\theta)$. Moreover, it is easy to see that $\sigma_1 f(\theta)$ is also the eigenvector of $U_0$. Thus, both $f^{(+))(\theta)} = f(\theta)$ and $f^{(-)(\theta)} = \sigma_1 f(\theta)$ are common eigenvectors of $U_0$ and $H_0$:

$$H_0 f^{(\pm)}(\theta) = \pm g(\theta) f^{(\pm)}(\theta),$$

(A.4)

$$U_0 f^{(\pm)}(\theta) = e^{i\theta} f^{(\pm)}(\theta).$$

(A.5)

Now, since $H_0 f^{(\pm)}(\theta) = g^2(\theta) f^{(\pm)}(\theta)$, with (A.3), we find

$$S_0 S_0^* f_{1/2}(\theta) = g^2(\theta) f_{1/2}(\theta).$$

(A.6)

From (22) and (24), this means

$$\int_{S_0} K_2(t, t') f_{1/2}(\theta, t') dt' = g^2 f_{1/2}(\theta, t).$$

(A.7)
with \( K_2 = S_c S_c^* \) and \( t \in \mathcal{S}_0 \), where we have explicitly eliminated the \( \theta \)-dependence of \( g \). Since \( K_2 \) is Hermitian \( L^2 \) [34], its eigenfunctions, \( \{ \psi_n(t) \} \), defined by

\[
\int_0^{T_0} K_2(t, t') \psi_n(t') \, dt' = g_n^2 \psi_n(t),
\]

(A.8)

form a complete orthonormal set. Thus, with (24), we find (29).

**Appendix B**

It is easy to see that the functions of the set \( \{ f_n(\theta, t) \} \) are orthonormal. To show the completeness, one first notes that for an arbitrary well-behaved function, say \( \alpha(t) \), its inverse Fourier transform can be written as

\[
\alpha(t) = \frac{1}{2\pi} \int_{-\infty}^{+\infty} \alpha(\omega) e^{i\omega t} \, d\omega
\]

\[
= \frac{1}{2\pi} \sum_k \int_{-\Omega_0/2}^{+\Omega_0/2} \alpha(\omega) e^{ik\Omega_0 \omega / T_0} e^{i\omega t} \, d\omega
\]

\[
= \frac{1}{2\pi} \sum_k e^{ik\Omega_0 \omega / T_0} \alpha_B(\omega, t) e^{i(t-kT_0)\omega / T_0} \, d\omega,
\]

where \( \Omega_0 = 2\pi T_0^{-1} \), and

\[
\alpha_B(\omega, t) = \frac{1}{2\pi} \sum_k e^{ik\Omega_0 \omega / T_0} \alpha(k\Omega_0 + \omega + \Delta_0 / T_0)
\]

is the so-called Bloch amplitude, which is \( T_0 \)-periodic. On the other hand, for each given \( \theta \), the set of functions \( \{ g_n(\theta, t) \} \), defined as

\[
g_n(\theta, t) = \sqrt{2\pi} f_n(\theta, t) e^{-i\Omega_0^{-1}(\theta+\Delta_0)t}
\]

\[
= \sum_{k=-\infty}^{+\infty} \psi_n(t - kT_0) e^{-i\Omega_0^{-1}(t - kT_0)(\theta+\Delta_0)}
\]

is \( T_0 \)-periodic and is a complete orthonormal basis for all \( T_0 \)-periodic functions due to the completeness of \( \{ \psi_n \} \). Thus, we can project \( \alpha_B(\omega, t) \) on the basis \( \{ g_n(\omega T_0, t) \} \):

\[
\alpha_B(\omega, t) = \sum_n \alpha_n'(\omega T_0) g_n(\omega T_0, t),
\]

with \( \alpha_n'(\omega T_0) = \int_{\mathcal{S}_0} g_n^*(\omega T_0, t) \alpha_B(\omega, t) \, dt \). Therefore,

\[
\alpha(t) = \int_{-\Omega_0/2}^{+\Omega_0/2} \sum_n \alpha_n'(\omega T_0) g_n(\omega T_0, t) e^{i(\omega+\Delta_0 / T_0)t} \, d\omega
\]

\[
= T_0^{-1} \int_{-\pi}^{+\pi} \sum_n \alpha_n'(\theta) g_n(\theta, t) e^{i\Omega_0^{-1}(\theta+\Delta_0)t} \, d\theta
\]

\[
= \frac{\sqrt{2\pi}}{T_0} \int_{-\pi}^{+\pi} \sum_n \alpha_n'(\theta) f_n(\theta, t) \, d\theta
\]

\[
= \int_{-\pi}^{+\pi} \sum_n \alpha_n(\theta) f_n(\theta, t) \, d\theta,
\]
where we have made the substitution $\theta \rightarrow \omega T_0$ in the second line, and
\[
\alpha_n(\theta) = \frac{\sqrt{2\pi}}{T_0} \alpha'_n(\theta) = \int_{-\infty}^{+\infty} f_n^*(\theta, t) \alpha(t) \, dt.
\]

So, we have shown that any well-behaved function, for which a Bloch amplitude exists, can be written as the combination of the functions of $\{ f_n(\theta, t) \}$. Thus, frequency combs indeed form a complete orthonormal set.

**Appendix C**

Since our system, evolving as (44), is in a mixed state, the quantum Fisher information should be evaluated as [33]
\[
F_N = \text{tr} \hat{\rho}^{(N)}(0) \hat{L}_N^2,
\]
where $\hat{L}_N$ is the symmetric logarithmic derivative that verifies
\[
\frac{1}{i}[\hat{L}_N \hat{\rho}^{(N)}(0) + \hat{\rho}^{(N)} \hat{L}_N] = i[\hat{\Omega}_N, \hat{\rho}_N(0)].
\]

We can replace $\hat{\Omega}_N$ by $\Delta \hat{\Omega}_N = \hat{\Omega}_N - \langle \hat{\Omega}_N \rangle$ in the above commutator. Assuming that the field is intense and $\tau$ is small, from (45), we have approximately
\[
\Delta \hat{\Omega}_N = \sqrt{2} \sum_{k=0}^{N-1} \sum_n \alpha'_n,k \Delta \hat{x}_{n,k},
\]

where $\alpha'_n,k = \sum_m \Omega_{n,m} \langle \hat{a}_{m,k} \rangle$ has been assumed to be real.

Since the sub-systems of supermodes are uncorrelated, $\hat{\rho}^{(N)}(0)$ can be written as a direct product of sub-systems: $\hat{\rho}^{(N)}(0) = \prod_{n=0}^{\infty} \hat{\rho}_n^{(N)}$, where $\hat{\rho}_n^{(N)}$ is the state of the $n$th supermode. It is convenient to project $\hat{\rho}_n^{(N)}$ on the eigenstates of the $p$-quadratures [25]:
\[
\hat{\rho}_n^{(N)} = \int_{\mathbb{R}^{2N}} |\tilde{p}\rangle \tilde{W}_n(\tilde{p}, \tilde{p}') \langle \tilde{p}'| \tilde{d}^N \tilde{p} \tilde{d}^N \tilde{p}',
\]
with
\[
\tilde{W}_n(\tilde{p}, \tilde{p}') = \int_{\mathbb{R}^N} d^N \tilde{x} W_n \left( \tilde{x}, \frac{\tilde{p} + \tilde{p}'}{2} \right) e^{-i\tilde{p}\cdot(\tilde{x} - \tilde{x}')},
\]
where $W_n(\tilde{x}, \tilde{p})$ is the Wigner function. For our case, it is a Gaussian function of $2N$ variables.
\[
W_n(\tilde{x}, \tilde{p}) = \frac{e^{-\frac{1}{4}(\Delta^2)^2 N^2(N) + \Delta \tilde{x}_n + \Delta \tilde{p}_n - \Delta \tilde{p}_n)}{2\pi \nu^2(N)} \frac{1}{2\pi \nu^2(N)}.
\]
where $\nu^2(N) = |V_{n}^{(N)}(N)|^{-1}$, and $\Delta \tilde{x}_n = \tilde{x} - \bar{x}_n$ and $\Delta \tilde{p}_n = \tilde{p} - \bar{p}_n$, with $\bar{x}_n$ and $\bar{p}_n$ being the mean values. Now, since $\langle p' | \tilde{x} | p \rangle = -i \partial_{\tilde{p}} \delta(p - p')$, we have from (4.4)
\[
\langle \tilde{p} | [\Delta \hat{x}_{n,k}, \hat{\rho}_n^{(N)}] | \tilde{p}' \rangle = i(\partial_{\tilde{p}_n} + \partial_{\tilde{p}'_n}) \tilde{W}_n(\tilde{p}, \tilde{p}')
\]
Then, it is straightforward to show that the symmetric logarithmic derivative reads

\[ \hat{L}_N = \frac{1}{\sqrt{2}} \sum_n \sum_{j,k=0}^{N-1} \Lambda_{n,(k,j)}^{(-)}(N) \alpha'_{n,k} \Delta \hat{p}_{n,j}. \]  

(C.8)

Hence, the quantum Fisher information (A.7) now reads

\[ F_N = \frac{1}{2} \sum_n \sum_{j,k=0}^{N-1} \Lambda_{n,(k,j)}^{(-)}(N) \alpha'_{n,k} \alpha'_{n,j}. \]
