We study the spontaneous motion, binary collisions, and collective dynamics of “polar disks”, i.e. purpose-built particles which, when vibrated between two horizontal plates, move coherently along a direction strongly correlated to their intrinsic polarity. The motion of our particles, although nominally three-dimensional and complicated, is well accounted for by a two-dimensional persistent random walk. Their binary collisions are spatiotemporally extended events during which multiple actual collisions happen, yielding a weak average effective alignment. We show that this well-controlled, “dry active matter” system can display collective motion with orientationally-ordered regions of the order of the system size. We provide evidence of strong number density in the most ordered regimes observed. These results are discussed in the light of the limitations of our system, notably those due to the inevitable presence of walls.

I. INTRODUCTION

Active matter is nowadays the expression designating out-of-equilibrium systems where energy is spent locally to produce directed motion [1]. Examples abound, at all scales and in many fields, with perhaps the most spectacular ones in living systems, from the motion of subcellular components to that of large animal groups [2–10]. Active matter is of course the word used by physicists, who have been flocking to this rather new, burgeoning field, producing novel theoretical ideas and results, and creating well-controlled objects that can move “on their own” either swimming in a fluid or crawling on a substrate [11–17]. Although the fluid is always there, it can sometimes be safely neglected, and momentum conservation thus disobeyed, in particular when objects are moving on a substrate, which acts as a momentum sink. One then speaks of “dry” active matter [1] [18].

Microscopic models of dry active matter usually consist of self-propelled particles whose local interactions give rise to some kind of alignment. This includes the now famous Vicsek et al. model in which constant-speed point particles align “ferromagnetically” with neighboring ones, in the presence of noise, in what amounts to an out-of-equilibrium version of the XY model [19]. Important results have been obtained recently both on microscopic models like the Vicsek model and on continuous descriptions of dry active matter [20–26]. These include the seminal calculation by Toner and Tu [27, 28] who confirmed, via a renormalization-group approach, the numerical findings of Vicsek et al. that collective motion can be sustained at all scales in spite of the presence of noise: true long-range orientational order exists even in two dimensions when spins are moving in space.

Although much remains to be done, progress has been recorded in matching the many numerical results obtained with microscopic models to their continuous descriptions [24–26, 29], and important theoretical predictions have been confirmed in numerical studies [21–23]. The situation is much less satisfactory at the experimental level. This should not be a surprise: living systems, be they large animal groups or collections of cells or even biofilaments and motor proteins, are difficult if not impossible to control, and they typically involve many extra, unwanted, and often unknown factors and mechanisms.

In this setting, building inert objects capable of moving by themselves or by capturing energy from their environment is a crucial step towards well-controlled experiments. In the context of dry active matter, two options are available: moving “robots” interacting by direct contact or at some distance via sensors [30], or asymmetric objects vibrated on some homogeneous substrate. Here we follow this last option, building on knowledge gathered over the last few decades on shaken granular media.

Yamada, Houhou, and Sano were pioneers in demonstrating that an axisymmetric polar object vibrated between two plates can move quasiballistically [31]. Kudrolli’s group studied the behavior of polar rods [32] and, more recently, of short snakelike chains [33]. Shaken elongated apolar particles (a realization of so-called active nematics) have been considered in [34].
FIG. 1. (color online) Vibrational system. (a) The vibration is provided by an electromagnetic servo-controlled shaker ballasted with lead and isolated from ground by rubber mats (4). It is then transmitted to the vibrating plate (2) via a brass rod coupled to a square air bearing (3). The vibrating plate (2) is composed of a nylon plate, an expanded polystyrene truncated cone, on top of which is glued the glass plate which supports the vibrated grains. Finally, the grains are confined vertically by a top glass plate fixed to an external rigid frame (1). (b) This top glass plate (1) is in a rigid frame (2), the vertical position of which is finely tuned by micro-control screws (3) to ensure an homogeneous gap of 2.4 mm. (c) The vibration is imposed and retro-controlled at the center of the glass plate supporting the grains. It is measured at the periphery of the plate. Vertical and azimuthal transfer functions between the acceleration imposed by the controller in the center of the plate and the one measured at six points on the plate perimeter. The horizontal dashed dark lines indicate a control of the acceleration within 5%. The vertical dot-dashed line indicates the frequency at which all experiments reported in this paper have been conducted.

The particles above are all elongated objects, with their asymmetry inscribed in their shape. This usually ensures that their (inelastic) collisions result in alignment, in a way after all rather similar to what happens in numerical models [35–38]. In this paper, we deliberately depart from this: we report further and at length on our experiments performed on vibrated polar disks, following a first account of their collective properties [39]. The asymmetry of our particles is thus not in their shape, but in their contact properties with the vibrating plate (both friction and restitution coefficient), which endows them, as we shall see, with rather unusual collision dynamics.

The rest of this paper is organized as follows: in Section II, we detail our vibration apparatus and the design of our polar disks. Section III is devoted to the description of the individual motion of our particles and how it varies with our main control parameter, the vibration amplitude. In Section IV, we show that collisions between two of our polar disks possess rather complicated properties, but they do result in some effective alignment. In Section V, we turn to the collective properties of our particles and show that our system can produce orientational order over large scales. Section VI contains a discussion of the limitations of our results and offers some perspectives on future work.
II. EXPERIMENTAL APPARATUS

In principle, producing some kind of self-propulsion using vibrating man-made objects allows for incomparably more control than with, say, biological organisms or even motility assays in which biofilaments are displaced by motor proteins grafted to a substrate. Nevertheless, in order to be free from various artifacts, these experiments require extremely homogeneous and strictly horizontal vibration, which is notoriously difficult to achieve. Indeed, previous attempts have been suspected of being plagued by large-scale spurious modes [34, 40, 41]. In this section, we first introduce the vibrational system we used to generate a well-controlled vertical vibration. We then describe and motivate the design of our polar disks.

A. Vibration system

The vibration is provided by an electromagnetic servo-controlled shaker (V455/6-PA1000L, LDS) [Fig.1a.], which rests on a thick wooden plate ballasted with 300 kg lead bricks and isolated from ground with rubber mats (MUSTshock 100x100xEP5). The vibration is transmitted to the vibrating plate via a 400 mm-long, 8 mm-thick brass rod, coupled with a stiff square air-bearing slider of size 127 mm (C40-03100-100254, IBSPE). The brass rod is flexible enough to compensate for the alignment mismatch, but stiff enough to ensure the mechanical coupling between the slider and the shaker. The slider ensures virtually friction-free and submicron amplitude horizontal motion. The plate is composed of a 50 mm thick nylon plate fixed to the slide, a 50 mm expanded polystyrene truncated cone, on top of which is glued the 425 mm diameter glass plate supporting the vibrated grains. Finally, the vertical motion of the grains is confined by a top glass plate attached to an external non vibrating rigid frame. The two glass plates are separated by a gap $h = 2.4$ mm.

An uniaxial accelerometer, used to control the vibration, is glued at the bottom of the bottom glass plate, inside a small cavity encarved in the polystyrene. In order to control the vibration quality, we measure with a triaxial accelerometer (356B18, PCB electronics) the vertical and azimuthal transfer functions between the controller and the acceleration recorded on the perimeter of the bottom glass plate, when vibrated at an acceleration $A_0 = 1$ g, where g stands for the acceleration of gravity [Fig.1b.]. A working frequency $f = 115$ Hz was chosen so that it avoids all resonances in the vibrating system while inducing motion of our polar disks (see below). At this frequency, the azimuthal to vertical acceleration ratio is smaller than 1% and the relative vibration heterogeneities are less than 5%.

B. Self-propelled particles

To the best of our knowledge, all previous experiments looking at the coherent displacement of objects colliding with a vertically-vibrated horizontally-homogeneous substrate have used elongated particles [31, 32]. In other words, the axis necessary to break rotational symmetry was simply encoded in the shape. Here, by contrast, we use essentially circular particles: they consist of a top metallic disk with two asymmetric “legs” aligned to give the object a polar axis (Fig. 2a). These particles interact strictly via their top circular hard parts, much like more conventional hard disks. Their polarity lies in the contacts with the vibrating plate.

In detail, we micro-machined copper-beryllium disks of diameter 4 mm and height 2 mm with an off-center leg to which a nitrile skate of hardness 90 Sh was glued at a diametrically opposite position (Fig. 2a). The skate is overmoulded to the copper-beryllium thanks to two polymeric layers, one adhesive to the metal (THIXON(TM) 520 Adhesive, Rhom and Haas), the other to the nitrile (THIXON P-11/0285SPL/25KG, Rhom and Haas). These two “legs”, which have different mechanical response under vibration, endow the particles with a polar axis which can be determined from above thanks to a black spot located on their top (Fig. 2b).

In the following we also use plain disks (same metal, diameter and height) as a control to ensure that all the effects reported here are indeed due to the “self-propulsion” induced by the built-in polarity.
C. Data acquisition

The position and polarity of the disks were recorded by a CCD camera with a spatial resolution of 1728x1728 pixels. The acquisition rate was set to 20 Hz or 25 Hz, i.e., about five times slower than the shaking frequency of 115 Hz. The ratio of the vibration frequency and the data acquisition rate sets the value of $\tau_0$, the smallest time increment accessible. The trajectory of each particle was then reconstructed using standard tracking software. In the following, the time unit is set to be the vibration period and the unit length is the particle diameter. Within these units, the resolution on the position $\vec{r}$ of the particles is better than 0.05, and that on the orientation $\vec{n}$ is of the order of 0.05 rad.

III. SINGLE PARTICLE MOTION

Our polar disks, once vibrated at $f = 115$ Hz in our apparatus, undergo fairly coherent, persistent motion of the particles, over some range of easily accessible amplitudes $\Gamma = \frac{A_0 \omega^2}{g}$ with $\omega = 2\pi f$.

A. Typical behavior

The single particle motion, which arises from the interplay of collision/friction of the two legs with the bottom plate, and of the metallic disk with the top plate, is too complicated to be described quantitatively. In the following, we only discuss its projection on the horizontal plane, “forgetting” about the three-dimensional nature of the events at its origin. Typical two-dimensional trajectories of isolated particles appear smooth and rather straight (Fig. 3a), as opposed to those of the control plain disks (Fig. 3b). A closer inspection, though, reveals that our polar particles typically move steadily forward for some time, but also intermittently stop or even move backward briefly (Fig. 3b) and Supplementary movie [42].

The directed, persistent motion of particles is recorded in the (discrete-)time series of their position $\vec{r}(t)$ and polarity $\theta(t)$. The polarity is very persistent in time: the distribution of $\Delta \theta(\tau) = \theta(t + \tau) - \theta(t)$, its increment over time $\tau$, is essentially exponential and sharply peaked at zero for $\tau = \tau_0$. Moreover, the distribution of the reduced increment $\Delta \theta(\tau)/\langle \Delta \theta(\tau)^2 \rangle^{1/2}$ remains roughly independent of $\tau$ up to fairly large values of $\tau$, after which it gradually recovers the expected asymptotic Gaussian character (Fig. 3c).

The directed, persistent motion of particles is recorded in the (discrete-)time series of their position $\vec{r}(t)$ and polarity $\theta(t)$. The polarity is very persistent in time: the distribution of $\Delta \theta(\tau) = \theta(t + \tau) - \theta(t)$, its increment over time $\tau$, is essentially exponential and sharply peaked at zero for $\tau = \tau_0$. Moreover, the distribution of the reduced increment $\Delta \theta(\tau)/\langle \Delta \theta(\tau)^2 \rangle^{1/2}$ remains roughly independent of $\tau$ up to fairly large values of $\tau$, after which it gradually recovers the expected asymptotic Gaussian character (Fig. 3c). The crossover value of $\tau$ (of the order of 100) can be taken as a rough estimate of the persistence time of polarity.

By and large, the displacement of the particles is overwhelmingly along their polarity axis: the distribution function of the angle $\alpha(\tau)$ between $\vec{r}(t, \tau) = \vec{r}(t + \tau) - \vec{r}(t)$, the displacement vector over time $\tau$, and $\theta(t)$ is peaked around zero. Strikingly, this is all the more so as $\tau$ is large: The backward motion events apparent in the secondary peaks at $\pm \pi$ present at small $\tau$ average out as $\tau$ is taken larger, an indication that during most of these “backward events” the polarity remains largely unchanged (Fig. 3d). Again, this is only true up to some...
The crossover value of $\tau \simeq 100$ beyond which the distribution of $\alpha(\tau)$ must gradually become flat. For $\tau$ larger than the crossover, one indeed observes a widening of the distribution. This displacement mostly along the polarity axis is performed at a fairly well-defined speed: for not too large $\tau$, the distribution of $|\Delta r(t, \tau)|/\tau$ is peaked around a most probable value. Increasing $\tau$ from $\tau_0$ to about the crossover time mentioned above, the distribution keeps the same most probable value and gets narrower and narrower (Fig. 3). The well-defined most probable value is thus nothing but the average speed $\langle v \rangle$. This indicates again that over these timescales our particles essentially go straight. The distribution is then essentially Gaussian. For timescales larger than the crossover, there is of course a shift of the “speed” towards lower values as expected when the particles enter the long-time, uncorrelated, diffusive regime.

### B. Influence of the vibration amplitude $\Gamma$

We have seen above that our polar disks can be faithfully described, over scales which average out the stopping and backward events, as moving at a well-defined finite speed $\langle v \rangle$ while being subjected to weak rotational diffusion. A direct and accurate measure of the (rather long) persistence length/time of the trajectories of our particles via, say, the time decay of the autocorrelation of their polarity, is rendered difficult by the relatively small size of our system. The data presented in Fig. 3 were obtained in a dish of diameter 40 vibrated at an amplitude $\Gamma = 2.8$. In such conditions, the rather straight trajectories will hit the wall long before their have turned enough to yield a significant decay of the polarity autocorrelation. To overcome this difficulty, we used the distribution of (normalized) polarity increments as shown in Fig. 3. Being independent of $\tau$ at small $\tau$, and the mean square angular increment being linear in $\tau$ (Fig. 4a), it allows to define the rotational diffusion constant $D_\theta$ as its (half-)variance, and thus the persistence length as $\xi = \langle v \rangle / D_\theta$.

The influence of $\Gamma$ on $V_m$, $D_\theta$, and $\xi$ is described in Fig. 4. First of all, we observe a rather sudden drop in self-propulsion when $\Gamma$ is decreased (Fig. 4a): for small amplitude, the drive is too weak and our polar disks do not move much. Over the range $\Gamma \in [2.7, 3.8]$, on the other hand, the average speed varies little. In contrast, the rotational diffusion constant $D_\theta$, which is easily captured from the root mean square angular increment computed on a lag $\tau$ (Fig. 4b), steadily increases with $\Gamma$, with an almost linear behavior in the $\Gamma$-range over which steady propulsion occurs (Fig. 4c). This indicates that the main effect of $\Gamma$ is on the strength of the angular noise. As a consequence, the persistence length $\xi$ becomes large as $\Gamma$ is decreased within the steady propulsion range [2.7, 3.8], but falls back for too small $\Gamma$ values (Fig. 4d).

![Graphs showing influence of $\Gamma$ on $V_m$, $D_\theta$, and $\xi$.](image)

(b) Mean square angular increment computed on a lag time $\tau$ versus $\Gamma$, for vibration amplitude $\Gamma \in [2.7 - 3.7]$. (c) Diffusion coefficient $D_\theta$ of the orientation of the polarity vs. $\Gamma$. (d) Persistence length $\xi = \langle v \rangle / D_\theta$ vs. $\Gamma$. Symbols (+) and (o) indicate two different experimental runs with different experimental conditions, such as ambient humidity, fine positioning of the top glass plate, etc.... The data analyzed in this paper for the small system correspond to the run labelled (+).

### IV. BINARY COLLISIONS

Having characterized the motion of our particles, we now turn to a statistical description of their binary collisions using trajectories recorded when only few particles are evolving in the system (typically 50 particles in a domain of diameter $\sim 40$). As already stated, most models for the collective motion of objects moving on a substrate involve more or less explicit alignment rules. For elongated, rod-like particles, inelastic collisions immediately lead to alignment. Here, given that our particles interact by collisions of their circular top part, no such direct alignment occurs. Rather, encounters typically consist of multiple collisions each followed by some rebounds (Fig. 5a and Supplementary movie [43]). It is thus by no means clear a priori that even some effective, average alignment takes place during collisions of two of our particles.
A. Defining collisions, their duration, and their spatial extent

Given that encounters of two of our particles typically involve many actual collisions, sometimes occurring more frequently than our sampling rate, we studied the statistics of encounters defined by the total space-time event during which two particles, initially far apart, have had their centers stay closer from each other than some threshold distance $d_c$. To ensure that these events are “real” collisions, this distance criterion was supplemented by the condition that the polarities of the two particles at the beginning of the encounter indicate that their distance is likely to decrease.

Obviously, $d_c$ must be chosen larger than 1, but not too large otherwise encounters may not cease. To use a unique, objective value of $d_c$, we calculated $\langle \tau_c \rangle$, the mean duration of encounters, as a function of $d_c$, over a set of a few thousands events. The resulting curve shows a plateau-like behavior in the range $d_c \in [1.5 - 1.9]$, the middle of which can be defined as being the inflection point $d_c^\dagger \simeq 1.7$ (Fig. 5c). Furthermore, this well-defined value, around which the statistics of encounters do not vary significantly, does not vary much when $\Gamma$ is changed within the useful range $[2.7, 3.8]$. It is thus adopted in the following to define encounters (hereafter renamed collisions for simplicity) quantitatively. Once collisions thus defined, their spatial extension $\Delta r_c$ can be estimated as the distance between the mid point of the particle centers at the beginning and at the end of the collision (Fig. 5b) We find the collision sizes distributed roughly algebraically with an exponent of the order of 3, whereas the collision durations $\tau_c$ are distributed roughly exponentially. The influence of $\Gamma$ on these distributions remains rather weak, with experimentally-observed means decreasing slowly with $\Gamma$ (Fig. 5d-f).
B. Alignment properties

In spite of their complicated space-time structure, and of the intrinsically chaotic/noisy character of the particle dynamics, the binary collisions possess a remarkable property: the sum of the polarities of the two particles changes very little between the beginning and the end of the collision. The distribution of the angle $\beta$ characterizing this (see Fig. 5b) is sharply peaked around 0 (Fig. 6c).

In the following, we thus assume that $\beta = 0$, and neglect the dependence of the collision statistics on the impact coefficient, so that all the information related to alignment is encoded in the conditional probability of $\theta_{\text{out}}$, the outgoing angle of the polarities, on $\theta_{\text{in}}$, the incoming angle (Fig. 5b). All this information is represented in the scatter plot of $\theta_{\text{out}}$ vs $\theta_{\text{in}}$ (Fig. 6d). A first striking fact is that most collisions actually do not change polarities at all: most points of the scatter plot are located near the diagonal $\theta_{\text{out}} = -\theta_{\text{in}}$; the distribution of $|\theta_{\text{out}} - \theta_{\text{in}}|$ is sharply peaked near zero (Fig. 6c). In the ($\theta_{\text{in}}, \theta_{\text{out}}$) scatter plot, apart from the highly-populated diagonal region, most of the remaining points are located near the $\theta_{\text{out}} = 0$ axis (near-perfect, Vicsek-style alignment) or in the triangular region between this axis and the $\theta_{\text{out}} = -\theta_{\text{in}}$ diagonal (reduced outgoing angle, but not perfect alignment) (see Fig. 6d). Anti-alignment or “nematic” interactions similar to that represented in Fig. 5b (bottom) can be seen, but they remain rare.

Thus, all in all, about 70% of binary collisions amount to no effective interaction. Among the 30% remaining ones, most are strongly aligning, with a few outliers. So far, our system seems to be rather close to the Vicsek model: our particles can be considered, on some coarse-grained timescale, to be moving at constant speed. Via the shaking amplitude $\Gamma$, we have good control on the effective rotational diffusion constant $D_\theta$. And binary collisions, when they significantly alter the orientation of particles, are clearly aligning.

This said, it is still by no means clear, in the higher density regimes where collective motion could arise, that any of these observations is really important. Indeed, one expects there short mean free paths, and very complicated, possibly unending collision events involving more than two particles, a usual feature of dense collections of finite-size granular particles made even more acute here by the fact that binary collisions are spatio-temporally extended events.

V. COLLECTIVE MOTION

We now turn to the study of the collective dynamics of our vibrated polar disks. We first discuss interactions between our particles and the lateral walls of our apparatus, as well as the choice of the size and shape of the horizontal domain in which they are evolving.

A. Domain size and shape, collisions with boundary

When one of our particles hits a wall head-on, it bounces on it repeatedly, gradually turning after each hit, and eventually escapes, typically along the wall (see a sketch in Fig. 7a). Thus, in a many-particle system, one expects an accumulation of particles near the wall, be it flat or circular. This is a common problem when dealing with self-propelled objects, as already experienced, e.g., by Kudrolli et al. [32]. In the “real world”, one cannot easily rely on the periodic boundary conditions available in numerical studies, short of having particles move on some closed surface like a sphere or a torus.

In the present case, we designed “flower-shaped” domains (Fig. 7b,c) to help particles escape from the wall. Crawling along a “petal”, they are likely to be reinjected in the bulk when reaching the cusp point marking the limit with the next petal: each arc behaves as a launch-pod. Two different flower-shaped arenas have been used in the following, one of internal diameter 40 and 8 petals (the “small” system) the other one of internal diameter 90 and 16 petals (the “large” system). The “petal” size was not scaled with the internal diameter, but was kept roughly constant: their arc radii are 9.3 for the small system, and 10.125 for the large one. Therefore, only the
The general available area increases when changing from the small to the large system, not the length-scale used to re-inject particles toward the center.

B. Packing fraction and region of interest

In the vast majority of models for collective motion, the ordered, collectively-moving phase is reached by either increasing the persistence length of the single particle walk (e.g., by reducing the angular noise strength) or increasing the density of particles (which make interactions frequent enough to sustain the memory of the last aligning collision until the next event).

In our system, we have seen that the persistence length is controlled rather nicely by the vibration amplitude \( \Gamma \). Clearly, this is the easiest control parameter to use here, since changing density would be tedious. But we already showed that the polar disks in our system can only move coherently on a rather restricted range of \( \Gamma \) values (in particular propulsion deteriorates quickly when \( \Gamma < 2.7 \)). This limit, in turn, imposes that we work at the “right” density of particles so that the transition to collective motion and the ordered phase be observable. If the density is too low, our system cannot order, even for \( \Gamma = 2.7 \). If it is too high, on the other hand, one is bound to run into the problem of glassy dynamics, crystallization and jamming: because of their finite size, our polar particles flock in packed clusters. Jamming of active particles is an interesting problem (on which research has just started [44, 45]), but it is beyond the “simpler”, Vicsek-style problem of collective motion of point particles considered here.

Thus, that collective motion is observable in our system is not guaranteed. We found, by trial and error, that nominal packing fractions \( \phi \) (the total area covered by the particles in the system divided by the domain area) in the range \( \phi \in [0.4, 0.6] \) give the best results. For instance, 890 particles in our “small” domain (\( \phi = 0.47 \)) vibrated at \( \Gamma = 2.7 \) move collectively on large scales in a spectacular way (Fig. 8a and Supplementary movie [46]).

In fact, the issues discussed above are further complicated by the effect of boundaries. Even if our flower-shaped domains help solve the problem of particle accumulation along the walls, they do not prevent it entirely, and we do observe, on average, higher densities near the wall (Fig. 8b). This forces us to define a “region of interest” (ROI) over which the observed time-averaged density remains approximately constant. From graphs like that of Fig. 8b, we see that the time-averaged density is constant to a few percent if the ROI is chosen to be of diameter 20, i.e. half the nominal diameter of our small system. For the range of packing fractions we will discuss below, we could safely use the same ROI size independently of the nominal packing fraction. Finally, going from our small domain (diameter 40) to the large one (diameter 90), we find that the ROI roughly doubles (from diameter 20 to 40) if one keeps the requirement of a few percent variation of the observed time-averaged density. Inside the ROI, the well-defined averaged packing fraction \( \phi_{ROI} \) is not only significantly smaller than the nominal packing fraction \( \phi \), but it decreases slowly with \( \Gamma \) (see inset of Fig 8d). (Note that these are opposite effects: decreasing \( \Gamma \) should increase order since this reduces \( D_{th} \), but lower \( \phi_{ROI} \) values should decrease it.) For the 890 particles in our small system, we observe that \( \phi_{ROI} \in [0.36, 0.42] \) for \( \Gamma \in [2.7, 3.7] \) (Fig. 8b).

With these remarks in mind, we now present results from three sets of experiments performed by varying \( \Gamma \) at fixed “geometrical conditions” (Table I).

| Experiment | Arena used | \# of particles | \( \phi \) | typical \( \phi_{ROI} \) |
|------------|------------|----------------|----------|-----------------|
| Ea         | small      | 890            | 0.47     | 0.39            |
| Eb         | large      | 3830           | 0.42     | 0.26            |
| Ec         | small      | 1090           | 0.58     | 0.19            |

C. Onset of collective motion

In experiments Ea and Eb, decreasing the vibration amplitude \( \Gamma \) brings the system from a disordered state to regimes where particles, in large regions of the system of the order of the ROI diameter, move in approximately the same direction (Fig. 8a and Supplementary movie [46]).

Different order parameters can be defined to quantify the degree of orientational order. The average polarity is easy to measure, but we preferred to use the average orientation of the displacement of each particle over a time \( \tau = 50 \), taken as a proxy for velocity. Although both choices yield essentially the same results, the latter one is more directly related to the transition to collective
FIG. 8. (color online) Emergence of collective motion: (a) Snapshot taken in a regime with long-range collective motion. The color code is red (rep. blue) for perfectly aligned (rep. anti-aligned) neighbors. (b) Time-averaged packing fraction $\langle \phi(r,t) \rangle_t$ versus the distance $r$ to the center of the vibrating plate for $\Gamma \in [2.7 - 3.7]$. The size of the region of interest (ROI) is chosen in order to ensure uniformity of the packing fraction inside the ROI and indicated by the vertical dashed line. The ROI in the small system has a radius of 10 particles diameters. We also checked that the packing fraction inside the ROI is stationary. (Same color code as in (c)) (c) Distribution of the order parameter $\Psi$ for $\Gamma \in [2.7 - 3.7]$, (color code as indicated in the legend). (d) Most probable value $\Psi_m$ of the order parameter as a function of $\Gamma$ for both the smaller experiment $E_a$ (black ◦) and the larger one, $E_b$, (red +). Inset: $\Phi_{ROI}$ as a function of $\Gamma$ for the same experiments. (e) Temporal evolution of the order parameter $\Psi(t)$ for four different vibration amplitudes $\Gamma = 3.6, 3.3, 3.1, 2.8$.

motion. Below, $\Psi(t)$ in fact represents the modulus of this velocity-based order parameter, properly normalized to be 1 for perfectly aligned particles.

Time series of $\Psi(t)$ show that decreasing $\Gamma$ from 3.7 to 2.7, the system reaches more and more ordered states, albeit never perfectly ordered ones as expected in a finite system with hard walls (Fig. 8b). The most ordered regimes exhibit very large fluctuations of the order parameter over very long timescales as shown also in the corresponding histograms of values taken by $\Psi(t)$ (Fig. 8c).

As a matter of fact, our limited range of usable $\Gamma$ values did not allow to reach regimes well inside the ordered phase, as shown, e.g., by the variation with $\Gamma$ of $\Psi_m$, the most probable value of the order parameter (Fig. 8d). In both experiments $E_a$ and $E_b$, $\Psi_m$ reaches values of the order of 0.5 for $\Gamma = 2.8$, but starts falling back for smaller $\Gamma$ values. In the experiment on the large system $E_b$, the rise a $\Psi_m$ seems steeper than in experiment $E_a$, but the two curves are in fact difficult to compare given that the two experiments possess different averaged packing fractions in their ROI.

Thus it is not clear from the variation of the order parameter alone whether our system, in its most ordered regime ($\Gamma = 2.8$), has reached the ordered phase or is still influenced by the transitional region. A direct measurement of the spatial and temporal correlation functions of the Eulerian velocity field suggests, though, that the ordered phase is indeed reached. The Eulerian velocity field is here defined on a grid with a square mesh of size 1x1. At each time step the local Eulerian velocity is the average of the instantaneous velocity of the particles, the center of which is inside one element of this mesh. For small-enough $\Gamma$ values, correlations in space
We measured number fluctuations in both experiments Ea and Eb for \(\Gamma = 2.8\). Given the variations of local average packing fraction described above, we used for \(n\) the mean number of particles actually recorded in each box in which particles were counted. This actually allowed us to use boxes slightly outside the ROI for better statistics without any detectable problem. As expected, \(\Delta n^2\) varies algebraically with \(n\) until it levels off at large \(n\) due to finite-size effects (Fig. 9c). The effective scaling exponent, measured over two decades, is \(\gamma = 1.40 \pm 0.01\) for experiment Ea and \(\gamma = 1.44 \pm 0.01\) for experiment Eb. This is close and below the expected theoretical value 1.6, in agreement with the observation that the asymptotic value is approached from below as the system size increases\([21]\).

E. Intermittent confinement-induced milling

Experiment Ec illustrates some of the consequences of increasing the density of particles. With a nominal packing fraction \(\phi = 0.58\), the ROI being fixed as previously to a diameter of 20, we observe an effective packing fraction inside the ROI \(\phi_{ROI} = 0.19\) suggesting a stronger concentration of the particles along the boundaries, which cannot be “ignored” anymore: the time series of \(\Psi\) in the ordered state observed at \(\Gamma = 3\) show an intermittent behavior between values of the order of 0.6 and values in the range \([0,0.3]\) (Fig. 10a-b). These low values do not indicate a disordered state. Rather, they are the trace of a milling configuration, i.e. a system-wide vortex obviously resulting from the domain shape (Fig. 10c-e and Supplementary movie 48). This can be quantified by calculating the macroscopic angular momentum \(H(t) = \langle \vec{n}_i(t) \vec{e}_{\theta_i}(t) \rangle\), where \(\vec{e}_{\theta_i}(t)\) is the azimuthal unit vector associated to \(\theta_i\), the angular position...
of particle $i$ in polar coordinates. Time series of $\Psi$ and $\Pi$ reveal that the system switches intermittently between clockwise and counterclockwise milling: $\Pi$ changes sign from time to time, but never dwells long around zero. The usual order parameter $\Psi$, in fact, takes large values mostly during these reversal events (Fig. 10a-b).

The transition scenario we have observed in experiments $E_a$ and $E_b$ and described in the previous section is thus strongly modified. Here when $\Gamma$ is decreased, one first observed the onset of collective motion, as in the previous case, but soon they organize in system size vortices and the transition towards polar order is interrupted. Further investigations are required to investigate the interplay between these two transitions. But one can already conclude that confined active flows are like any confined flows: boundaries cannot be ignored, and it is hard to disentangle the intrinsic “bulk” properties of active fluids from those resulting from the inevitable presence of boundaries.

VI. SUMMARY AND DISCUSSION

Our results constitute, to our knowledge, the first study of a well-controlled experimental system in which “self-propelled” objects are able to move collectively over scales as large as the system size. The dynamics of our particles, although nominally three-dimensional and complicated, is well accounted for by a two-dimensional description in terms of persistent random walks. Their binary collisions are not simple inelastic aligning ones, but are spatiotemporally extended events during which multiple actual collisions happen, leading eventually to a weak but clear effective alignment.

At the collective level, we showed how to avoid the accumulation of particles near the boundary walls by adopting flower-shaped arenas whose petals help reinject particles in the bulk. This trick is of course not perfect, and we do observe higher average densities near the walls, so that take must be taken in defining a region of interest in which the density is nearly constant although different from the nominal packing fraction. We presented the results of three sets of experiments conducted near “optimal” densities such that well-developed collective
motion is observed, in which orientational order is established on scales comparable to the system size. In these most ordered regimes, we recorded clear, unambiguous evidence of “giant number fluctuations”, a signature feature of orientationally-ordered phases in active matter.

From the wealth of numerical studies of models of active matter, where periodic boundary conditions are often adopted, it is easy to forget about the inevitable role played by walls when investigating collective motion. Here, in addition to the subtle effects about the effective packing fraction recorded in the region of interest, we showed that at densities slightly larger than those used in the regimes where giant number fluctuations were recorded, the boundaries “come back” in the problem by driving macroscopic vortical flows.

The experiments we conducted have also shown some clear limitations of our setup: Even though we used two domain sizes, finite-size effects remain strong and difficult to estimate, which rules out any statement about the (asymptotic) nature of the transition to collective motion. Also, because our particles cease to move below some vibration amplitude value, we could not explore regimes “deep in the ordered phase”. Thus, to be true, it is hard to disentangle, in the strong density fluctuations measured, those intrinsic to the ordered phase from those linked to the proximity of the transition (not to mention again finite-size effects). Moreover, recent theoretical progress has shown that the ordered phase, in a parameter region bordered by the transition, is generically difficult. Reverting to the study of large swarms of small robots [49], or to biological motility assays [3], would suppress limitations in domain size, but at the price of some lesser control. Another approach, that we are currently pursuing [50], is to study in silico the system sizes and boundary conditions experimentally inaccessible by constructing a numerical model faithful to every experimental finding. Obviously, such a model cannot be yet another Vicsek-style model. It has to incorporate ingredients such as the treatment of the polarity vs. velocity dynamics, and to account for the complex series of collisions typically observed when two particles meet. It is our hope that such a model could give us access to the truly large-scale behavior of our system, and maybe, unveil new asymptotic properties.

We thank M. van Hecke for advice in the design of our system, V. Padilla and C. Gasquet for technical assistance, and E. Bertin for enlightening discussions. This work was supported by the French ANR project Dy-CoAct.
