ABSTRACT

Ten herd-level cross-sectional studies were conducted in peri-urban dairy production areas of seven West and Central African countries (Burkina Faso, Burundi, Cameroon, Mali, Niger, Senegal and Togo). The objectives were to estimate herd level Brucella spp. seroprevalence and identify risk factors for seropositivity.

In each of the ten study areas, herds (between 52 and 142 per area, total=965) were selected probabilistically and a structured questionnaire was administered to gather information on their structure and management. A bulk milk sample from each herd was tested by indirect ELISA for Brucella spp. For each area, herd seroprevalence estimates were obtained after adjusting for the assumed performance of the diagnostic test. Herd level risk factors for Brucella spp. seropositivity were identified by means of stratified logistic regression, with each peri-urban zone as a stratum. Area-specific models were also explored. Estimated herd seroprevalence estimates were obtained after adjusting for the assumed performance of the diagnostic test. Herd level risk factors for Brucella spp. seropositivity were identified by means of stratified logistic regression, with each peri-urban zone as a stratum. Area-specific models were also explored. Estimated herd seroprevalence estimates were obtained after adjusting for the assumed performance of the diagnostic test. Herd level risk factors for Brucella spp. seropositivity were identified by means of stratified logistic regression, with each peri-urban zone as a stratum. Area-specific models were also explored.

Estimated herd seroprevalences were: Lomé (Togo) 62.0% (95% CI:55.0–69.0), Bamako (Mali) 32.5% (95% CI:28.0–37.0), Bujumbura (Burundi) 14.7% (95% CI:9.4–20.8), Bamenda (Cameroon) 12.6% (95% CI:7.6–21.9), Ouagadougou (Burkina Faso) 3.0% (95% CI:1.9–5.1), Ngaoundere (Cameroon) 2.3% (95% CI:1.9–7.0), Thies (Senegal) 1.3% (95% CI:0.5–5.3), Niamey (Niger) 1.2% (95% CI:0.8–5.3), Dakar (Senegal) 0.2% (95% CI:0.1–1.7) and Niakhar (Senegal) < 0.04%. Logistic regression modelling revealed transhumant herds to be at lower risk of infection (adjusted OR: 0.25, 95% CI: 0.13 - 0.5) and in one of the areas (Bamenda), regular purchase of new animals was found to be strongly associated with Brucella spp. seropositivity (adjusted OR = 5.3, 95% CI: 1.4–25.9). Our findings confirm that Brucella spp. circulates among dairy cattle supplying milk to urban consumers in West and Central Africa, posing a serious public health concern. Control programs
1. Introduction

Globally, brucellosis is assumed to represent one of the highest economic and public health burdens of any zoonosis, with Brucella melitensis, B. abortus, B. suis and B. canis all producing disease in human and animal populations (Corbel, 2006; Whatmore et al., 2014; Al Dahouk et al., 2017). Ruminants are the primary hosts for B. melitensis and B. abortus, with humans becoming infected following consumption of raw milk and dairy products, by direct contact with aborted foetuses, afterbirth and parturition fluids and during slaughter practices (FAO, 2010; WHO, 2005; Doganay and Aygen, 2003).

In humans, the acute form of the disease is debilitating with general malaise, fever, arthralgia and backache reducing a patient’s ability to work. An acute brucellosis episode has an estimated disability weight (DW) of 0.210, highlighting the high impact of brucellosis on individuals (Dean et al., 2012;WHO, 2015). The World HealthOrganisation (WHO) estimated that in 2010 there were 0.83 million cases of human brucellosis globally (47% of these were identified as foodborne in origin) although the actual figure is likely to be much higher than this, due to widespread under-reporting and misdiagnosis (WHO, 2015; Kirk et al., 2015; Jennings et al., 2007).

In 2011, the World Bank ranked brucellosis among the top ten diseases globally for all the main domestic ruminant species in terms of Livestock Units Lost (LUL; World Bank, 2011). Losses are the result of abortions and associated reduction in milk yield (McDermott et al., 2013; Oseguera Montiel et al., 2015). In cattle, the disease is mainly associated with the species B. abortus, which has been successfully eliminated from Australia, New Zealand, Canada, Japan and several European countries through the vaccination of susceptible animals, followed by a test-and-slaughter policy (CFSPH, 2009).

West and Central Africa are rapidly-urbanising regions, with an increased demand for dairy products being met by a burgeoning dairy sector, largely located in the peri-urban areas that surround major cities (Ducrotoy et al., 2017; Guneralp et al., 2017). Brucellosis is suspected to be endemic throughout the region, although the lack of prevalence estimates, together with various practical and political factors at both local and regional levels, have left brucellosis in livestock largely uncontrolled (Akakpo et al., 2009; Alonso et al., 2016; Craighead et al., 2017). Although the available evidence is scarce and should be interpreted with caution, previous studies have shown high levels of infection among dairy herds located in dairy production areas in West and Central Africa. In Mali for example it was estimated in 2003 that up to 30% of milk and dairy products at selling points in Bamako were contaminated with Brucella (Bonfoh et al., 2003). More recently, in 2014, it was estimated that 25.6% of dairy herds in the Adamawa and North Regions of Cameroon were seropositive against Brucella spp. (Awah-Ndukum et al., 2018). Lack of brucellosis control programs is particularly worrying in expanding dairy systems, in which husbandry practices are known to favour disease spread (Ogugua et al., 2018). Furthermore, the absence of milk hygiene controls and sociocultural habits of unpasteurized dairy product consumption, common in Sub-Saharan Africa, amplify the potential public health impact of Brucella infection in these settings. An initial step towards the formulation of locally-appropriate brucellosis control programmes is the characterization of the infection status of dairy farms. Thus, the objectives of this study were to provide herd-level estimates of Brucella spp. seroprevalence among bovine dairy herds in ten of the major peri-urban dairy zones across West and Central Africa and identify herd-level risk factors for seropositive status against Brucella spp.
2. Methods

2.1. Study design and study population

Cross-sectional studies were conducted in ten peri-urban dairy production zones across seven West and Central Africa countries between February 2017 and January 2018, in Burkina Faso (Ouagadougou), Burundi (Bujumbura), Cameroon (N’Djaména and Bamenda), Mali (Bamako), Niger (Niamey), Senegal (Dakar, Thies and Niakhar) and Togo (Lomé) (Fig. 1).

The target population was defined as ‘all bovine dairy herds present in the predefined peri-urban zone’. The study unit was defined as ‘any herd where lactating cows are managed together as a unit regardless of herd size’. For this purpose, all lactating cows kept together, owned by the same person/household and usually kept in the same location were included. The most commonly practised livestock production systems in the region are sedentary, unrestricted grazing and transhumant livestock production and very few herds are of the nomadic type (SWAC-OECD/ECOWAS, 2008). For purpose of this study, peri-urban dairy production zones were broadly defined as areas of concentration of dairy farms in the proximity of urban areas to which they supply milk/dairy products. The geographical boundaries for each ‘peri-urban dairy production zone’ were defined through discussion with personnel from the veterinary and livestock production services, dairy farm associations and private veterinarians in each zone by delimiting on a map the area where ‘most’ farms concentrate. The size of the areas ranged from 333 km² (Lomé) to 7069 km² (N’Djaména).

Ethical approval was granted by the Ethics and Welfare Committee of the Royal Veterinary College (RVC) and the Ethics Committee at the Interstate School of Veterinary Science and Medicine of Dakar (EISMV). Informed consent for questionnaire administration and collection of biological samples was obtained verbally from herd owners before sampling and interviewing. Each study was conducted using the same protocol and any departures from protocol were recorded.

2.2. Sampling frame, sampling strategy and sample size calculations

Where available, a comprehensive list of all known dairy herds within each zone was used as the sampling frame. Where such lists were unavailable, a snowballing approach was used among local milk collectors and sellers to identify dairy herds in the zone. Sampling began once no new herds could be identified.

Using an expected herd-level prevalence of 15%, based on previously published data (Akakpo et al., 2009; Boukary et al., 2013), it was calculated that sampling between 60 and 90 herds per zone would result in an absolute precision of 5% with 95% confidence in populations of between 125 and 250 herds.

\[
n_i = \frac{1.96^2 \times P \times (1 - P)}{d^2}
\]

Table 1

| Country       | Zone           | Number of dairy herds in the list (Sampling frame) | Data source     |
|---------------|----------------|---------------------------------------------------|-----------------|
| Burkina Faso  | Ougadougou     | 129                                               | Snowballing     |
| Burundi       | Bujumbura      | 157                                               | Veterinary services |
| Cameroon      | N’Djaména      | 301                                               | Veterinary services |
|               | Bamenda        | 304                                               | Veterinary services |
| Mali          | Bamako         | 160                                               | Veterinary services |
| Senegal       | Dakar          | 150                                               | Veterinary services |
|               | Thies          | 147                                               | Veterinary services |
|               | Niakhar        | 170                                               | Veterinary services |
| Togo          | Lomé           | 176                                               | Snowballing     |
| Niger         | Niamey         | 135                                               | Snowballing     |

2.3. Collection and testing of milk samples

Milk samples were collected in 50 ml sterile screw cap polyethylene tubes with 5 ml of 5% formalin added immediately. Where available, a bulk milk sample was collected, otherwise a small volume of milk from each lactating cow was collected into a single container and 50 ml of milk taken from this mix. Milk samples were kept chilled in a cool box with ice before arrival at the diagnostic laboratory, where they were centrifuged, aliquoted into 1 ml units and frozen at −20 °C for storage.

Once all sample collection in a zone had been completed, samples were brought to room temperature and tested for Brucella spp. antibodies using Brucelisa160 M indirect ELISA (iELISA; assays provided by the OIE brucellosis reference centre Animal and Plant Health Agency (APHA), Addlestone, Surrey, UK). The cut-off optical density (OD) was calculated at 50% of the mean value of the eight intermediate control wells. All samples with an OD equal to or above the cut-off value were considered positive. Testing of the milk samples was carried out in six different diagnostic laboratories across the study countries. For the purpose of quality control, testing procedure was standardised across all laboratories with positive and negative controls provided. Moreover, the raw OD data and photos of all ELISA plates where inspected by the first author, who decided acceptance of the results of each ELISA plate.

2.4. Data collection

A structured questionnaire was administered at the time of sampling using Open Data Kit (ODK) on Android tablets in a choice of English or French. Herd name, location, composition (number of lactating cows,

bulls and heifers), husbandry and management practices were all recorded. A pilot questionnaire was administered in ten herds in the study area of Dakar, then modified accordingly to form the final version (see Table 2 for variables recorded). Training and written guidelines were provided to all staff before commencing data collection and questions were posed by a bilingual administrator using the local language.

2.5. Data analysis

2.5.1. Seroprevalence estimation

Apparent herd level seroprevalence (AP) was calculated for each zone by dividing the total number of seropositive herds by the total number of herds sampled. True seroprevalence (TP) for each zone was then calculated by adjusting for iELISA sensitivity (Se) and specificity (Sp) values as:

$$TP = \frac{(AP + Sp - 1)}{(Se + Sp - 1)}$$

According to the manufacturer the Se and Sp values for the iELISA are 0.98 and 0.99, respectively. Exact 95% confidence intervals (CI) for estimated true seroprevalences were obtained based on sampling from the hypergeometric distribution implemented in @Risk 7.5 for Excel (Palisade Corporation Inc., Newfield, NY, USA).

2.5.2. Univariable analysis

Univariable associations between potential risk factors and the herd serological status were assessed for each of the four highest seroprevalence zones (Lomé, Bamako, Bujumbura and Bamenda), each zone was considered separately. Associations were not assessed for the remaining six areas because of the low number of positive herds. Serological status was considered as either positive or negative. Adult herd size was categorized as either ≤ median or > median. Associations between individual risk factors and the herd serological status were assessed using the Chi-squared test of association.

2.5.3. Multivariable analysis

Significant explanatory variables in the univariate analysis ($p \leq 0.05$) were assessed for collinearity using Cramer’s phi prime statistic ($\phi$) with variables considered collinear where $\phi > 0.7$, when a pair of variables was found to be collinear, only the more biologically plausible variable was kept for multivariable analysis.

Multivariable analyses were conducted, first, independently for each of the four zones with highest prevalence and secondly for all zones simultaneously in a stratified model. For the analysis by zone, variables were first examined individually using a univariable logistic model and selected when $p \leq 0.2$. Selected variables were then included in a logistic model and manual backward elimination was used to obtain a final model, with the least significant variables removed, providing their removal did not alter the odds ratios (OR) of other variables by more than 20% and $p \geq 0.05$. Analyses were also conducted using forward selection, starting with the variables with lowest $p$ values in the univariable analysis. Adjusted OR and 95% confidence intervals (CIs) were obtained, with variables only retained if $p < 0.05$.

For the analysis of all zones simultaneously, stratified logistic regression was used, with herd serological status a binary outcome and zone as stratum. The model was built using the same steps described above for the analysis by zone.

Univariable and multivariable data analyses were carried out using R version 3.5.1 (R Core Team, 2018) and stratified logistic regression

### Table 3

| Country  | Zone          | No. of herds sampled | No. (%) tested positive by milk iELISA | No. of questionnaires completed |
|----------|---------------|----------------------|----------------------------------------|-------------------------------|
| Burkina Faso | Ouagadougou | 52                   | 1 (2.8)                                | 52                            |
| Burundi  | Bujumbura     | 87                   | 14 (16.1)                              | 87                            |
| Cameroon | Bujumbura     | 100                  | 14 (14)                                | 96                            |
| Cameroon | Ouagadougou   | 142                  | 4 (2.8)                                | 98                            |
| Mali     | Bamako        | 120                  | 40 (33.3)                              | 66                            |
| Niger    | Niamey        | 80                   | 2 (2.5)                                | 49                            |
| Senegal  | Niamey        | 89                   | 1 (1.1)                                | 89                            |
| Senegal  | Thies         | 76                   | 2 (2.6)                                | 76                            |
| Togo     | Lomé          | 100                  | 62 (62)                                | 77                            |
| TOTAL    |               | 965                  | 140 (14.5)                             | 809                           |

analysis was performed using the function `clogit` implemented in R package `survival`.

### 3. Results

#### 3.1. Seroprevalence estimates

Bulk milk samples were collected from 965 herds in 10 study zones and questionnaires completed from 809 herds (84%) (Table 3). Estimated herd-level seroprevalences for the highest four peri-urban zones were: Lomé (Togo) 62.0% (95% CI: 55.0–69.0), Bamako (Mali) 32.5% (95% CI: 28.0–37.0), Bujumbura (Burundi) 14.7% (95% CI: 9.4–20.8) and Bamenda (Cameroon) 12.6% (95% CI: 7.6–21.9), Fig. 2.

#### 3.2. Risk factors

Median adult herd size, minimum, maximum and median number of lactating cows, heifers and bulls in addition to husbandry and management practices for the 10 peri-urban zones are presented in Table 2. Univariable analyses showed the practice of transhumance to be significantly associated with lower risk of positive serological status both in Bamenda and Bujumbura. Also in Bamenda, the regular purchase of new animals during the previous year was significantly associated with higher risk of seropositivity, and the mixing of cattle with other livestock during watering or grazing was marginally associated with higher risk of seropositivity (Table 4).

In the multivariable analyses, transhumance remained a protective factor in both Bujumbura (adjusted OR: 0.24, 95% CI: 0.07–0.8, \( p = 0.02 \)) and Bamenda (adjusted OR: 0.17, 95% CI: 0.05–0.6, \( p = 0.01 \)). In Bamenda, regular purchasing of new animals in the previous year was also found to be strongly associated with seropositivity (adjusted OR: 5.3, 95% CI: 1.4–25.9, \( p = 0.02 \)). Logistic regression modelling with zone included as a strata revealed transhumance to be a protective factor (adjusted OR: 0.25, 95% CI: 0.13–0.5, \( p < 0.01 \)), no other factor was identified as significantly associated with the risk of seropositivity (Table 5).

#### 4. Discussion

Our results confirm that brucellosis is widespread among the peri-urban bovine dairy supply chains of West and Central Africa, which presents a serious public health threat to local populations, particularly urban bovine dairy supply chains of West and Central Africa, which were: Lomé (Togo) 62.0% (95% CI: 55.0–69.0), Bamako (Mali) 32.5% (95% CI: 28.0–37.0), Bujumbura (Burundi) 14.7% (95% CI: 9.4–20.8) and Bamenda (Cameroon) 12.6% (95% CI: 7.6–21.9), Fig. 2.

Positive herds were found in all study areas except for one (Niakhar in Senegal). Herd-level seroprevalence values vary considerably between areas.

The high herd seroprevalences found in some areas, such as Lomé and Bamako, are compatible with a high human disease burden, although currently limited, data are available to confirm this (Bonfok et al., 2003; Akakpo et al., 2009; Dean et al., 2013; Craighead et al., 2017; Kanoute et al., 2017; Awah-Ndukum et al., 2018). Reasons for the large variation in seroprevalence remain unclear, however differences in management practices (e.g. source of replacement cows), farming systems (e.g. intensive vs. traditional) and variations in climate (e.g. the environmental persistence of Brucella spp. being influenced by wet and dry seasons lengths) are all likely to be contributory factors (Ducrotoy et al., 2017; Craighead et al., 2017).

For the purpose of sample size calculations we have used a value of 15% for the expected herd-level seroprevalence, based on most recent published data. Considerably higher values of herd-level seroprevalence were obtained in Lomé and Bamako. As a result, the precision of the estimate in these two areas is lower than expected and the confidence intervals are broader (Fig. 2). When comparing our prevalence values with those from other studies it should be noted that the adjustment of apparent prevalence to obtain ‘true’ prevalence was done assuming sensitivity and specificity values of 0.98 and 0.99 respectively (the values provided by the OIE brucellosis reference centre at the APHA, UK).

Within a given zone, the main factor that emerged as associated with increased risk of seropositive status is the farming system (transhumant vs. sedentary): sedentary herds are at significantly higher risk of infection in two of the four areas (Bujumbura and Bamako). A potential explanation for this is that sedentary dairy farming creates more favourable conditions for Brucella spp. transmission around the calving areas compared to transhumant farming. This is consistent with Ducrotoy’s hypothesis that transhumance, among other factors, mitigates the transmission of brucellosis in sub Saharan Africa (Ducrotoy et al., 2017). In this study we focused on dairy herds providing milk to urban areas and located in what we defined as a peri-urban zone. The high proportion of study herds found to practice transhumance in some of the zones may therefore appear to be unexpected. However, this is in agreement with the findings of the Sahel and West Africa Club (SWAC) and the Commission of the Economic Community of West African States (ECOWAS) study where transhumance was recognised as a regional phenomenon across geographic areas and production systems (including peri-urban farming) in West and Central African countries.

### Table 4

Descriptive statistics and univariable associations between potential herd level risk factors and Brucella spp. seropositivity in peri-urban dairy herds in Lomé (Togo), Bamako (Mali), Bujumbura (Burundi) and Bamenda (Cameroon). Results from a cross-sectional study conducted between January 2017 and February 2018.

| Variables                          | Togo (Lome) | Mali (Bamako) | Burundi (Bujumbura) | Cameroon (Bamenda) |

AI = Artificial insemination; NI = Natural insemination.
Regular purchase of new animals into the herd was found to be a significant risk factor for herd seropositivity in Bamenda, highlighting the risk of introduction of animals of unknown disease status in endemic areas and the need to test animals coming onto the farm and promote the use of home bred replacement cows where possible (Kanoute et al., 2017). Exploration of the relationship between the proportion of positive herds in an area and the density of dairy herds and animals within the area did not show any clear pattern, although the area with highest prevalence (Togo) had also the highest density at both, herd and individual animal level.

In our study we did not explicitly address the urban-rural interface, however, given how common transhumance is in some of the areas, it is likely that there is frequent contact and potentially transmission between herds providing milk and dairy products to urban areas and herds with production destined for home consumption in rural areas. Some studies previously conducted in the region have shown higher prevalence of bovine brucellosis in rural areas compared to urban and peri-urban areas, this was explained by the free animal movement in the rural area (Boukary et al., 2013). In East Africa, prevalence estimates of human brucellosis in rural, peri-urban and urban areas of Kampala, Uganda revealed higher number of human cases in the urban area (Boukary et al., 2013). In West Africa, prevalence of bovine brucellosis in peri-urban and rural areas of the rural area (Boukary et al., 2013) it seems reasonable to assume that Brucella is circulating in these zones. There is no brucellosis control program in place in any of the study areas, therefore, the status of dairy herds supplying milk to urban consumers in West and Central Africa, posing a serious public health concern. There is an urgent need for control programs, which have been proved effective at markedly reducing prevalence of brucellosis in cattle in different countries, to be an urgent need for the region. Further steps to facilitate action towards vaccine-based control include improvements in local diagnostic capability, strain isolation and characterization and vaccination trials.
