(Dated: August 28, 2015)

Motivated by the recent discovery of superconductivity in the iron-based ladder compound BaFe$_2$S$_3$ under high pressure, we derive low-energy effective Hamiltonians from first principles. We show that the complex band structure around the Fermi level is represented only by the Fe 3$d_{xz}$ (mixed with 3$d_{yz}$ and 3$d_{x^2−y^2}$ orbitals). The characteristic band degeneracy allows us to construct a four-band model with the band unfolding approach. We also estimate the interaction parameters and show that the system is more correlated than the 1111 family of iron-based superconductors.

Provided the superconductivity is mediated by spin fluctuations, the 3$d_{xz}$-like band plays an essential role, and the gap function changes its sign between the Fermi surface around the $Γ$ point and that around the Brillouin-zone boundary.

I. INTRODUCTION

Since the discovery of superconductivity in fluorine doped LaFeAsO$_x$, a variety of iron pnictides and chalcogenides have been found to exhibit superconductivity with high transition temperatures ($T_c$). In these compounds, Fe ions commonly form a two-dimensional (2D) network. This fact raises an intriguing and fundamental question whether the square network is essential for the high $T_c$ superconductivity and what happens in different geometries. In the case of the cuprates, it was discovered that the ladder compound (Sr,Ca)$_2$Cu$_4$O$_{11}$ becomes a superconductor under pressure $\sim$ 3 GPa. This experimental observation has stimulated various theoretical studies on superconductivity in quasi-1D systems. Interestingly, it has been recently found that a ladder compound BaFe$_2$S$_3$ becomes a superconductor under high pressure $\sim$ 10GPa. In the phase diagram, the superconducting phase resides next to a magnetic insulating phase, in which the spin correlation is antiferromagnetic along the ladder and ferromagnetic along the rung. The maximum $T_c$ is as high as 14 K. The superconducting transition in BaFe$_2$S$_3$ is of great interest, since we may have a chance to pin down the origin/mechanism of the high $T_c$ superconductivity in iron-based superconductors (FeSC) by investigating the commonalities and differences between the 2D and quasi-1D systems.

Recently, motivated by the experimental works on superconductivity in the single-layer potassium-doped iron selenide (110) film (which can be viewed as a weakly coupled ladder system) or ladder compounds such as BaFe$_2$Se$_3$ and CsFe$_2$Se$_3$ (which do not exhibit superconductivity), a variety of theoretical studies have been reported. However, studies for BaFe$_2$S$_3$ based on ab initio calculation are yet to be performed. In this study, we derive low-energy effective Hamiltonians for BaFe$_2$S$_3$ from first principles, focusing on the Fe 3$d$ bands around the Fermi level ($E_F$). We find that a $d_{xz}$-like orbital, a linear combination of $d_{xz}$ and $d_{xy}$, forms two Fermi (electron) pockets around $k_z=0$ and a $d_{x^2−y^2}$-like orbital forms a Fermi (hole) pocket around $k_z=\pi$.

The effective energy bands obtained with the two orbital models are further depicted in the unfolded Brillouin zone (BZ), in which one of the electron pockets is placed around the BZ boundary of $k'_z=\pi$. Since the magnetic instability is strong at $q'_z ∼ \pi$ in the extended BZ, the $d_{xz}$-like orbital should be active for spin-fluctuation-mediated superconductivity. We also estimate the values of interaction parameters in the effective Hamiltonian, such as the Hubbard $U$ and Hund’s coupling $J$. We show that BaFe$_2$S$_3$ is more strongly correlated than the 1111 compounds.

II. CRYSTAL STRUCTURE

In Fig. 1 we show the crystal structure of BaFe$_2$S$_3$. We see that Fe atoms form two-leg ladders running along the c-axis. In the following calculation for ambient pressure, we used the lattice constants $a$, $b$, and $c$ and the atomic positions of Ba, Fe and S reported in Ref. 14. Namely, the lattice constant $a$, $b$, and $c$ are 8.78, 11.23 and 5.29 Å, respectively. The space group is Cmcm, and the atomic positions of Ba(4c), Fe(8e), S(4c) and S(8g) are (0.0, 0.686, 0.25), (0.154, 0.0, 0.0), (0.0, 0.116, 0.25) and (0.208, 0.378, 0.25), respectively. In the phase diagram of temperature ($T$) and pressure ($P$), the superconducting phase has a dome-like shape and $T_c$ is highest around $P$=12.4 GPa. For $P$=12.4 GPa, $a$, $b$ and $c$ shrink to 96.0%, 92.0% and 96.6% of those at ambient pressure, respectively. Since the atomic configuration under pressure is yet to be reported, in the present calculation, we just change the lattice constants.
Since the unit cell contains four Fe atoms, there are four Fe 3$d$ orbitals in the unit cell. The wave functions are expanded by plane waves up to a cutoff energy of 40 Ry, and an 8×8×8 k-mesh in the first Brillouin zone is used.

Based on the band calculation, we further constructed Wannier functions for these bands using the wannier90 package. The resulting spreads of the $d_{3z^2-r^2}$, $d_{xz}$, $d_{yz}$, and $d_{xy}$ orbitals are 2.35, 3.51, 3.13, 2.40 and 3.14 Å$^2$ for ambient pressure, and 2.91, 4.01, 3.35, 2.73 and 3.43 Å$^2$ for $P=12.4$ GPa. If we compare the Wannier spreads of the 2D FeSC (Table III in Ref. 25), we see that at $P=0$ the Wannier functions are as localized as those of LiFeAs, but at $P=12.4$ GPa they are more delocalized as those of BaFe$_2$As$_2$.

In Fig. 2 we show the band dispersion obtained by the Wannier interpolation (blue dashed curves) with that from the density functional calculation (red solid curves). Since the unit cell contains four Fe atoms, there are twenty Fe 3$d$ bands around the Fermi level. We see that the band width of the Fe 3d states for $P=12.4$ GPa is larger than that for $P=0$ by ~25%. We list the resulting hopping integrals in the Supplemental Material. As is expected from the crystal structure shown in Fig. 1, the band structure is dispersive along the $k_z$ axis (from the $\Gamma$ to $Z$ point). The transfer integral is largest between the nearest neighbor $d_{3z^2-r^2}$ orbitals along the ladder (the $c$-axis), and its amplitude is ~0.56 eV. For $P=12.4$ GPa, it becomes 0.64 eV. These values are larger than the nearest-neighbor transfer integrals for the 2D FeSC (see Tables IV-VII in Ref. 25). On the other hand, the inter-ladder transfer integrals are small, so that the band structure of BaFe$_2$S$_3$ is quasi-one dimensional along the $k_z$ axis. Nevertheless, since the dominant transfer integrals along the $c$ axis are large, the band width of BaFe$_2$S$_3$ turns out to be a similar value to that of 2D FeSC (see Fig. 4 in Ref. 25). As for the onsite energies of $d_{3z^2-r^2}$, $d_{xz}$, $d_{yz}$, and $d_{xy}$, they are 7.44, 8.00, 8.03, 7.69, and 7.95 eV (where $E_F=8.19$ eV) for $P=0$, and 9.37, 10.02, 9.98, 9.62 and 9.89 eV (where $E_F=10.22$ eV) for $P=12.4$ GPa. The size of the crystal field splitting is similar to that of the 2D FeSC.

In Fig. 3 we show the Fermi surface for $P=0$. There are two electron pockets around $k_z=0$, hereafter called $\alpha$ and $\beta$, and one hole pocket around $k_z=\pi$, called $\gamma$. For $P=12.4$ GPa, the $\beta$ pocket significantly shrinks, while the $\alpha$ pocket is quite robust against the external pressure. The energy band lying just below $E_F(=0$ eV hereafter) around the $T$ points at $P=0$ crosses the Fermi level under pressure, resulting in another tiny pocket for $P=12.4$ GPa.

We plot the projected density of states for the 3d orbital.
While the amplitude of \( d_y \) is quite high, \( d_x \) in the direction perpendicular to the Fe plane as \( \sim 0.75 \) (see Table II in Ref. 25), and the orbital extends to the side of the pocket from \( \Gamma \) has a dominant \( x^2−y^2 \) character.

Interestingly, we can further simplify the current model by unfolding the BZ, as was done for the 1111 original BZ) consists of two orbitals, i.e. \( d_{x^2−y^2} \) and \( d_{x^2} \), respectively. To construct the Wannier functions, the inner (outer) window is set to be \([-0.3 \text{ eV}, 0.2 \text{ eV}] \) \((-1.2 \text{ eV}, 1.5 \text{ eV})\). We hereafter call the Wannier functions \( w_{x^2−y^2} \) and \( w_{xz} \). To construct the Wannier functions, the inner (outer) window is set to be \([-0.3 \text{ eV}, 0.2 \text{ eV}] \) \([-1.2 \text{ eV}, 1.5 \text{ eV}]\). In Fig. 4, we compare the orbital character of the Fermi surface of \( \text{BaFe}_2\text{S}_3 \) does. So far, several studies have pointed out that \( d_{3z^2−r^2} \) in the 2D FeSC does not play a crucial role in the magnetism and superconductivity.\(^{27–30}\)

**IV. TWO-ORBITAL MODEL AND BZ UNFOLDING**

We now further try to simplify the five-orbital (twenty-band) model. We have found that the energy dispersion around \( E_F \) can be represented by a two-orbital (eight-band) model in which the Wannier functions are mainly composed of two orbitals, i.e. \( d_{x^2−y^2} \) and \( d_{xz} \), hybridized with \( d_{xy} \). We hereafter call the Wannier functions \( w_{x^2−y^2} \) and \( w_{xz} \). To construct the Wannier functions, the inner (outer) window is set to be \([-0.3 \text{ eV}, 0.2 \text{ eV}] \) \([-1.2 \text{ eV}, 1.5 \text{ eV}]\) with respect to \( E_F \). In Fig. 6(a), we compare the original \( \text{ab initio} \) bands and the Wannier interpolated bands for ambient pressure. We obtained a similar result for \( P=12.4 \) GPa (not shown). We list the resulting hopping integrals for the two-orbital model in the Supplemental Material.\(^{29}\)

Interestingly, we can further simplify the current model by unfolding the BZ, as was done for the 1111 compound.\(^{22}\) Indeed, if we introduce a local gauge transformation for one of the two orbitals to change its sign, we can expand the band dispersion from \( \Gamma \) to \( Z \) (see Fig. 4(b))\(^{33}\). Then the model is simplified to a four-band model.

**V. LINDHARD FUNCTION**

In the 2D FeSC, both the hole and electron pockets consist of more than two orbitals. Here let us look at the orbital character of the Fermi surface of \( \text{BaFe}_2\text{S}_3 \). While the amplitude of \( d_y \) is quite high, \( d_x \) in the direction perpendicular to the Fe plane as \( \sim 0.75 \) (see Table II in Ref. 25), and the orbital extends to the side of the pocket from \( \Gamma \) has a dominant \( x^2−y^2 \) character.

In the 2D FeSC, the Lindhard function \( \chi^0(q) \) has a peak around \((\pi,0,0)\) and \((0,\pi,0)\) in the extended BZ,\(^{34–41}\) which is compatible with the stripe-type antiferromagnetic order. This fact has caused hot debates on which of the localized spin picture or the itinerant picture is more appropriate for describing the magnetic properties of 2D FeSC.\(^{36–41}\) Thus it is interesting to see whether the peak position of \( \chi^0(q) \) for \( \text{BaFe}_2\text{S}_3 \) agrees with the Bragg peak observed in the experiment.

In Fig. 5, we plot \( \chi^0(q) \) for the five-orbital model in the extended Brillouin zone. Here \( i \) and \( j(=1,2) \) specify the Fe atom in the unit cell. We see that the correlation along the ladder \((i=j)\) is stronger than that along the rung \( i \neq j \), and \( \chi^0(q) \) does not depend on \( q_x \) and \( q_y \) significantly. As for the \( q_z \) dependence, \( \chi^0(q) \) has larger values in the plane of \( q_z^2 = \pi \) than \( q_z^2 = 0 \), due to the nesting between the \( \alpha \) and \( \beta \) pockets in Fig. 3. Note that the \( \beta \) pocket moves to the plane of \( q_z^2 = \pi \) in the extended Brillouin zone. For \( P=12.4 \) GPa, although the \( \beta \) pocket shrinks, we confirmed that the contribution from the particle-hole scattering between \( \alpha \) and \( \beta \) is still dominant. This \( q_z^2 \) dependence of \( \chi^0(q) \) is consistent with the experiment in that the intra-orbital spin correlation is antiferromagnetic along the ladder. As for the correlation...
VI. SUPERCONDUCTIVITY

Since the superconducting phase resides next to the antiferromagnetic phase, let us here assume that the superconductivity is mediated by spin fluctuations. Then the pairing interaction is strong at $q' = \pi$, and favors a pairing gap function having different signs between the Fermi pockets $\alpha$ and $\beta$. The active band for superconductivity is $w_{xz}$ in this scenario, because both $\alpha$ and $\beta$ are made from $w_{xz}$. On the other hand, $w_{x^2-y^2}$ makes a pocket around $q' = \pm \pi/2$, but should be passive for the superconductivity. In the 2D FeSC, it has been proposed that $d_{xy}$ is important to understand the material dependence of the superconducting transition temperature$^{12,17}$ It is interesting to note that both $w_{xz}$ in BaFe$_2$S$_3$ and $d_{xy}$ in the 2D FeSC extend in the direction of pnictogen/chalcogen sites, and almost half-filled in the five-orbital model.

For 2D FeSC, the orbital fluctuation mechanism has been extensively studied$^{45-52}$ While it is an interesting future problem to study whether orbital fluctuations mediate superconductivity in BaFe$_2$S$_3$, there is a notable difference between the quasi-1D and 2D systems. In the case of the 2D FeSC, $d_{xz}$ and $d_{yz}$ are essential for the orbital-fluctuation mechanism. While these orbitals correspond to $d_{xy}$ and $d_{yz}$ in BaFe$_2$S$_3$, these are irrelevant in the two-orbital model.

VII. ELECTRON CORRELATIONS

Let us move on to the electron correlations in BaFe$_2$S$_3$. By means of the constrained random phase approximation (cRPA)\textsuperscript{53}, we estimate the values of the Hubbard $U$ and the Hund’s coupling $J$ in the five-orbital model. We used the density response code of Elk\textsuperscript{54,55}. In the calculation of the charge susceptibility, we took 100 unoccupied bands and $4 \times 4 \times 4$ $k$ and $q$ meshes. The double Fourier transform of the charge susceptibility was done with the cutoff of $|G+q|=2,3,4,5$ and 6 (1/a.u.) with $G$ being the reciprocal vector, from which we estimated the values extrapolated to the limit of $|G+q| \to \infty$. In Table I, we list the resulting values of $U$ and $J$ for $P=0$. If we compare these values (and the ratio $J/U$, which is important to measure the electron correlations in 2D FeSC\textsuperscript{53}) with those of the 2D FeSC\textsuperscript{22,55}, we see that they are as strong as those of LiFeAs. The pressure dependence of $U$ and $J$ is not so strong and they become smaller only by $\sim 6-7\%$ under the pressures up to $P=12.4$ Pa. These results suggest that BaFe$_2$S$_3$ is more strongly correlated than the 1111 compounds\textsuperscript{45,56} This observation is consistent with the fact that the ordered moment of BaFe$_2$S$_3$ is about 1.3 $\mu_B$, which is larger than that of LaFeAsO\textsuperscript{56,57}.
TABLE I: Hubbard $U$ and Hund’s $J$ in the five-orbital model for $P=0$ GPa.

| $U$ [eV] | $xy$ | $yz$ | $3z^2-r^2$ | $xz$ | $x^2-y^2$ |
|----------|------|------|-------------|------|------------|
| $xy$     | 3.35 | 2.42 | 2.34        | 2.33 | 3.16       |
| $yz$     | 2.42 | 3.26 | 2.89        | 2.30 | 2.54       |
| $3z^2-r^2$ | 2.34 | 2.89 | 3.79        | 2.77 | 2.44       |
| $xz$     | 2.33 | 2.30 | 2.77        | 2.99 | 2.43       |
| $x^2-y^2$ | 3.16 | 2.54 | 2.44        | 2.43 | 3.86       |

| $J$ [eV] | $xy$ | $yz$ | $3z^2-r^2$ | $xz$ | $x^2-y^2$ |
|----------|------|------|-------------|------|------------|
| $xy$     | 0.50 | 0.67 | 0.48        | 0.48 | 0.22       |
| $yz$     | 0.67 | 0.32 | 0.46        | 0.46 | 0.55       |
| $3z^2-r^2$ | 0.48 | 0.32 | 0.30        | 0.30 | 0.71       |
| $xz$     | 0.48 | 0.46 | 0.30        | 0.51 |            |
| $x^2-y^2$ | 0.22 | 0.55 | 0.71        | 0.51 |            |

VIII. CONCLUSION

We have studied the electronic structure of BaFe$_2$S$_3$ from first principles. Detailed analysis of the full Fe orbital model revealed that the Fermi surfaces are represented only by the two Fe orbitals, i.e. $w_{xz}$ and $w_{x^2-y^2}$. Provided that the superconductivity is mediated by spin fluctuations, $w_{xz}$, which corresponds to $d_{xy}$ in the 2D FeSC, is essential for superconductivity. In fact, they have the following common features: (i) they extend in the direction of pnictogen/chalcogen sites, (ii) they are nearly half-filled, (iii) they form disconnected Fermi pockets around $\Gamma$ and near the boundary of the BZ, between which pairing interaction mediated by stripe-type antiferromagnetic spin fluctuation works effectively. Concerning the electron correlations, it is stronger than those of LaFeAsO or LaFePO.
