Longest Segment of Balanced Parentheses:
an Exercise in Program Inversion in a Segment Problem

Shin-Cheng Mu, Tsung-Ju Chiang
Institute of Information Science, Academia Sinica, Taiwan

Abstract

Given a string of parentheses, the task is to find the longest consecutive segment that is balanced, in linear time. We find this problem interesting because it involves a combination of techniques: the usual approach for solving segment problems, and a theorem for constructing the inverse of a function — through which we derive an instance of shift-reduce parsing.

1 Introduction

Given a string of parentheses, the task is to find a longest consecutive segment that is balanced. For example, for input "))))))))))))" the output should be "((()())()"). We also consider a reduced version of the problem in which we return only the length of the segment. While there is no direct application of this problem, the authors find it interesting because it involves two techniques. Firstly, derivation for such optimal segment problems (those whose goal is to compute a segment of a list that is optimal up to certain criteria) usually follows a certain pattern (e.g. Bird [1987], Gibbons [1997], Zantema [1992]). We would like to see how well that works for this case. Secondly, at one point we will need to construct the right inverse of a function. It will turn out that we will discover an instance of shift-reduce parsing.

Specification

Balanced parentheses can be captured by a number of grammars, for example $S \rightarrow \varepsilon \mid (S) \mid SS$, or $S \rightarrow T^*$ and $T \rightarrow (S)$. After trying some of them, the authors decided on

$$S \rightarrow \varepsilon \mid (S) S,$$

because it is unambiguous and the most concise. Other grammars have worked too, albeit leading to lengthier algorithms. The parse tree of the chosen grammar can be represented in Haskell as below, with a function pr specifying how a tree is printed:

```haskell
data Tree = Nul | Bin Tree Tree
pr :: Tree -> String
pr Nul = ""
pr (Bin t u) = "(" ++ pr t ++ " + " ++ pr u ++ " + ")"
```

However, the length-only version was possibly used as an interview problem collected in, for example, https://leetcode.com/problems/longest-valid-parentheses/.
For example, letting \( t_1 = \text{Bin Nul Nul} \) and \( t_2 = \text{Bin Nul (Bin Nul Nul)} \), we have \( \text{pr } t_1 = "("", \text{pr } t_2 = "((")" \) and \( \text{pr } (\text{Bin } t_2 \text{ } t_1) = "((())")" \) (parentheses are colored to aid the reader).

Function \( \text{pr} \) is injective but not surjective: it does not yield un-balanced strings. Therefore its right inverse, that is, the function \( \text{pr}^{-1} \) such that \( \text{pr} \circ \text{pr}^{-1} \circ \text{pr} \circ \text{pr}^{-1} \circ \text{pr} \circ \text{pr}^{-1} = \text{pr} \), is partial; its domain is the set of balanced parenthesis strings. We implement it by a function that is made total by using the \( \text{Maybe} \) monad. This function \( \text{parse} :: \text{String} \rightarrow \text{Maybe Tree} \) builds a parse tree for string \( \text{parse } xs \) should return \text{Just } t \) such that \( \text{pr } t = xs \) if \( xs \) is balanced, and return \text{Nothing} \) otherwise. While this defines \( \text{parse} \) already, a direct definition of \( \text{parse} \) will be presented in Section 4.

The problem can then be specified as below, where \( \text{lbs} \) stands for “longest balanced segment (of parentheses)”: 

\[
\text{lbs} :: \text{String} \rightarrow \text{Tree} \\
\text{lbs} = \text{maxBy size} \circ \text{filtJust} \circ \text{map parse} \circ \text{segments} \\
\text{segments} = \text{concat} \circ \text{map inits} \circ \text{tails}, \\
\text{filtJust } t s = [t | \text{Just } t \leftarrow \text{ts}] \\
\text{size } t = \text{length } \text{pr } t
\]

The function \( \text{segments} :: [a] \rightarrow [[a]] \) returns all segments of a list, with \( \text{inits}, \text{tails} :: [a] \rightarrow [[a]] \) respectively computing all prefixes and suffixes of their input lists. The result of \( \text{map parse} \) is passed to \( \text{filtJust} :: \text{Maybe a} \rightarrow [a] \), which collects only those elements wrapped by \text{Just}. For example, \( \text{filtJust } [\text{Just } 1, \text{Nothing}, \text{Just } 2] = [1,2] \). For this problem \( \text{filtJust} \) always returns a non-empty list, because the empty string, which is a member of \( \text{segments } xs \) for any \( xs \), can always be parsed to \text{Just Nul}. Given \( f :: a \rightarrow b \) where \( b \) is a type that is ordered, \( \text{maxBy } f :: [a] \rightarrow a \) picks a maximum element from the input. Finally, \( \text{size } t \) computes the length of \( \text{pr } t \).

The length-only problem can be specified by \( \text{lbsl} = \text{size } \cdot \text{lbs} \).

2 The prefix-suffix decomposition

It is known that many optimal segment problems can be solved by following a fixed pattern [Bird, 1987, Gibbons, 1997, Zantema, 1992], which we refer to as \( \text{prefix-suffix decomposition} \). In the first step, finding an optimal segment is factored into finding, for each suffix, an optimal prefix. For our problem, the calculation goes:

\[
\text{maxBy size } \cdot \text{filtJust } \cdot \text{map parse } \cdot \text{segments} \\
= \{ \text{definition of segments} \} \\
\text{maxBy size } \cdot \text{filtJust } \cdot \text{map parse } \cdot \text{concat } \cdot \text{map inits } \cdot \text{tails} \\
= \{ \text{since map } f \cdot \text{concat } = \text{concat } \cdot \text{map } (\text{map } f), \text{map fusion} \} \\
\text{maxBy size } \cdot \text{filtJust } \cdot \text{concat } \cdot \text{map } (\text{map parse } \cdot \text{inits}) \cdot \text{tails} \\
= \{ \text{since filtJust } \cdot \text{concat } = \text{concat } \cdot \text{map filtJust} \} \\
\text{maxBy size } \cdot \text{concat } \cdot \text{map } (\text{filtJust } \cdot \text{map parse } \cdot \text{inits}) \cdot \text{tails} \\
= \{ \text{since maxBy } f \cdot \text{concat } = \text{maxBy } f \cdot \text{map } (\text{maxBy } f) \} \\
\text{maxBy size } \cdot \text{map } (\text{maxBy size } \cdot \text{filtJust } \cdot \text{map parse } \cdot \text{inits}) \cdot \text{tails}.
\]

For each suffix returned by \text{tails}, the program above computes its longest \text{prefix} of balanced parentheses by \( \text{maxBy size } \cdot \text{filtJust } \cdot \text{map parse } \cdot \text{inits} \). We abbreviate the latter to \text{lbp} (for “longest balanced prefix”).

2 \text{filtJust} is called \text{catMaybes} in the standard Haskell libraries. The authors think the name \text{filtJust} is more informative.
Generating every suffix and computing \( lbp \) for each of them is rather costly. The next step is to try to apply the following \textit{scan lemma}, which says that if a function \( f \) can be expressed as right fold, there is a more efficient algorithm to compute \( \text{map } f \cdot \text{tails} \):

\textbf{Lemma 1} \( \text{map } (\text{foldr } (\oplus) e) \cdot \text{tails} = \text{scanr } (\oplus) e \), where

\[
\text{scanr } (\oplus) e \; [\text{ ]} = \left[ \begin{array}{c}
\text{Just } e
\end{array} \right]
\]

\[
\text{scanr } (\oplus) e \; (x : xs) = \text{let } (y : ys) = \text{scanr } (\oplus) e \; xs \; \text{in } (x \oplus y) : y : ys .
\]

If \( lbp \) can be written in the form \( \text{foldr } (\oplus) e \), we do not need to compute \( lbp \) of each suffix from scratch; each optimal prefix can be computed, in \text{scanr}, from the previous optimal prefix by \((\oplus)\). If \((\oplus)\) is a constant-time operation, we get a linear-time algorithm.

The next challenge is therefore to express \( lbp \) as a right fold. Since \textit{init}s can be expressed as a right fold — \( \text{init}s = \text{foldr } (\lambda x \; xs \rightarrow [\text{ ]} : \text{map } (x:) \; xs) \; [\text{ ]} \), a reasonable attempt is to fuse \( \text{maxBy size filterJust } \cdot \text{map parse} \) with \textit{init}s, to form a single \text{foldr}. Recall the \text{foldr}-fusion theorem:

\textbf{Theorem 2 (foldr-fusion)} \( h \cdot \text{foldr } f \; e = \text{foldr } g \; (h \; e) \) if \( h \; (f \; x \; y) = g \; x \; (h \; y) \).

The antecedent \( h \; (f \; x \; y) = g \; x \; (h \; y) \) will be referred to as the \textit{fusion condition}. To fuse \textit{map parse} and \textit{init}s using Theorem 2, we calculate from the LHS of the fusion condition (with \( h = \text{map parse} \) and \( f = (\lambda x \; xs \rightarrow [\text{ ]} : \text{map } (x:) \; xs) \)):

\[
\text{map parse } ([\text{ ]} : \text{map } (x:) \; xs) \\
= \left[ \begin{array}{c}
\text{map parse } ([\text{ ]}) \\
\text{Just Nul : map } (\text{parse } \cdot (x:)) \; xs
\end{array} \right]
\]

\[
= \left[ \begin{array}{c}
\text{wishes for some } g' \\
\text{Just Nul : } g' \; x \; (\text{map parse } xs)
\end{array} \right]
\]

\[
= \left[ \begin{array}{c}
\text{let } g \; x \; ts = \text{Just Nul : } g \; x \; ts \\
\text{g } x \; (\text{map parse } xs)
\end{array} \right]
\]

We can construct \( g \) if (and only if) there is a function \( g' \) such that \( g' \; x \; (\text{map parse } xs) = \text{map } (\text{parse } \cdot (x:)) \; xs \). Is that possible?

It is not hard to see that the answer is no. Consider \( xs = [\text{""}, \text{""}, \text{""}] \) and \( x = \text{"'} \). Since both strings in \( xs \) are not balanced, \text{map parse } xs \) gives us \([\text{Nothing}, \text{Nothing}]\). However, \( \text{map } (x:) \; xs = [\text{""}, \text{""}, \text{""}] \), a list of balanced strings. Therefore \( g' \) has to produce something from nothing — an impossible task. We have to generalise our problem such that \( g' \) receives inputs that are more informative.

### 3 Partially Balanced Strings

A string of parentheses is said to be \textit{left-partially balanced} if it may possibly be balanced by adding zero or more parentheses to the left. For example, \( xs = \text{"'(())()"} \) is left-partially balanced because \textit{txbr} \((\text{"'} + xs \) is balanced — again we use coloring to help the reader parsing the string. Note that \((\text{"'} + xs \) is also balanced. For a counter example, the string \( ys = \text{"()()"} \) is not left-partially balanced — due to the unmatched \( \text{"'} \) in the middle of \( ys \), there is no \( zs \) such that \( zs + ys \) can be balanced.

While parsing a \textit{fully balanced} string cannot be expressed as a right fold, it is possible to parse \textit{left-partially balanced} strings using a right fold. In this
section we consider what data structure such a string should be parsed to. We discuss how to parse it in the next section.

A left-partially balanced string can always be uniquely factored into a sequence of fully balanced substrings, separated by one or more right parentheses. For example, \( xs \) can be factored into two balanced substrings, "(())()" and "()", separated by ")". One of the possible ways to represent such a string is by a list of trees — a \textit{Forest}, where the trees are supposed to be separated by a ')'. That is, such a forest can be printed by:

\[
\text{type Forest = [Tree], } (-\text{ non-empty -})
\]

\[
\begin{align*}
prF ::& \text{Forest} \rightarrow \text{String} \\
prF [t] &= pr \ t \\
prF (t : ts) &= pr \ t + "\)" + prF ts 
\end{align*}
\]

For example, \( xs = "((()))())()" \) can be represented by a forest containing three trees:

\[ ts = [txtl (Bin (Bin Nul Nul) (Bin Nul Nul)), Nul, txbl (Bin Nul Nul)] \]

where \( txtl (Bin (Bin Nul Nul) (Bin Nul Nul)) \) prints to "(())()", \( txbl (Bin Nul Nul) \) prints to "()", and there is a \textit{Nul} between them due to the consecutive right parentheses ")" in \( xs \) (\textit{Nul} itself prints to ""). One can verify that \( prF ts = xs \) indeed. Note that we let the type \textit{Forest} be \textit{non-empty} lists of trees.

The empty string can be represented by \([\text{Nul}]\), since \( prF [\text{Nul}] = pr \text{Nul} = "" \).

The aim now is to construct the right inverse of \( prF \), such that a left-partially balanced string can be parsed using a right fold.

4 PARSING PARTIALLY BALANCED STRINGS

Given a function \( f :: b \rightarrow t \), the converse-of-a-function theorem [Bird and de Moor, 1997, de Moor and Gibbons, 2000] constructs the relational converse — a generalised notion of inverse — of \( f \). The converse is given as a relational fold whose input type is \( t \), which can be any inductively-defined datatype with a polynomial base functor. We specialise the general theorem to our needs: we use it to construct only functions, not relations, and only for the case where \( t \) is a list type.

\textbf{Theorem 3} Given \( f :: b \rightarrow [a] \), if we have \( base :: b \) and \( step :: a \rightarrow b \rightarrow b \) satisfying:

\[
\begin{align*}
f base &= [] \\
f (step \ x \ t) &= x : f \ t,
\end{align*}
\]

then \( f^{-1} = \text{foldr step base} \) is a partial right inverse of \( f \). That is, we have \( f (f^{-1} xs) = xs \) for all \( xs \) in the range of \( f \).

While the general version of the theorem is not trivial to prove, the version above, specialised to functions and lists, can be verified by an easy induction on the input list.

Recall that we wish to construct the right inverse of \( prF \) using Theorem 3. It will be easier if we first construct a new definition of \( prF \), one that is inductive, does not use (+), and does not rely on \( pr \). For a base case,

\[\text{We can let the non-emptiness be more explicit by letting Forest = (Tree, [Tree])}.\] Presentation-wise, both representations have their pros and cons, and we eventually decided on using a list.
\( prF [\text{Nul}] = ""\). It is also immediate that \( prF (\text{Nul}:ts) = \)' : prF ts \). When the list contains more than one tree and the first tree is not \( \text{Nul} \), we calculate:

\[
prF (\text{Bin } t u : ts)
= \{ \text{definitions of } pr \text{ and } prF \}
= " + pr t + " + pr u + " + prF ts
= \{ \text{definition of } prF \}
= '(:prF (t : u : ts).
\]

We have thus derived the following new definition of \( prF \):

\[
prF [\text{Nul}] = ""
prF (\text{Nul}:ts) = ' : prF ts
prF (\text{Bin } t u : ts) = '(:prF (t : u : ts).
\]

We are now ready to invert \( prF \) by Theorem 3, which amounts to finding \( \text{base} \) and \( \text{step} \) such that \( prF \text{ base} = "" \) and \( prF (\text{step } x \ ts) = x : prF \ ts \) for \( x = ' ( \) \) or \( ' ) \). With the inductive definition of \( prF \) in mind, we pick \( base = [\text{Nul}] \), and the following \( \text{step} \) meets the requirement:

\[
\text{step } ' ) ' ts = \text{Nul} : ts
\text{step } ' ( ' (t : u : ts) = \text{Bin } t u : ts.
\]

We have thus constructed \( prF^{-1} = \text{foldr } \text{step} [\text{Nul}] \). If we expand the definitions, we have

\[
prF^{-1} :: \text{String} \rightarrow \text{Forest}
prF^{-1} "" = [\text{Nul}]
prF^{-1} (') : xs = \text{Nul} : \text{prF}^{-1} \ xs
prF^{-1} (\text{case } \text{prF}^{-1} \ xs \ of \ (t : u : ts) \rightarrow \text{Bin } t u : ts,
\]

which is pleasingly symmetrical to the inductive definition of \( prF \).

For an operational explanation, a right parenthesis \( ' ) \) indicates starting a new tree, thus we start freshly with a \( \text{Nul} \); a left parenthesis \( ' ( \) ought to be the leftmost symbol of some \( " (t)u " \), thus we wrap the two most recent siblings into one tree. When there are no such two siblings (that is, \( prF^{-1} \ xs \) in the \text{case} expression evaluates to a singleton list), the input \( ' ( : xs \) is not a left-partially balanced string — \( ' ( \) appears too early, and the result is undefined.

Readers may have noticed the similarity to shift-reduce parsing, in which, after reading a symbol we either "shift" the symbol by pushing it onto a stack, or "reduce" the symbol against a top segment of the stack. Here, the forest is the stack. The input is processed right-to-left, as opposed to left-to-right, which is more common when talking about parsing. We shall discuss this issue further in Section 7.

We could proceed to work with \( prF^{-1} \) for the rest of this pearl but, for clarity, we prefer to make the partiality explicit. Let \( \text{parseF} \) be the monadified version of \( prF^{-1} \), given by:

\[
parseF :: \text{String} \rightarrow \text{Maybe } \text{Forest}
parseF "" = \text{Just } [\text{Nul}]
parseF (x : xs) = \text{parseF } xs \gg \text{stepM } x,
\]

where \[
\text{stepM } ' ) ' ts = \text{Just } (\text{Nul} : ts)
\text{stepM } ' ( ' [t] = \text{Nothing}
\text{stepM } ' ( ' (t : u : ts) = \text{Just } (\text{Bin } t u : ts),
\]

\( \text{stepM} \) is a monad function that processes the stack (list) in a manner similar to \( \text{step} \), but for \( \text{parseF} \) we use \( \text{Maybe} \) to handle the possibility of an undefined result.
where \( \text{stepM} \) is monadified \( \text{step} \) — for the case \([t]\) missing in \( \text{step} \) we return \( \text{Nothing} \).

To relate \( \text{parseF} \) to \( \text{parse} \), notice that \( \text{prF} [t] = \text{pr} t \). We therefore have

\[
\text{parse} :: \text{String} \rightarrow \text{Maybe Tree}
\]

\[
\text{parse} = \text{unwrapM} <\text{parseF}, \text{unwrapM}[t] = \text{Just t}
\]

\[
\text{unwrapM} = \text{Nothing}
\]

where \( (<\text{c}) :: (b \rightarrow M c) \rightarrow (a \rightarrow M b) \rightarrow (a \rightarrow M c) \) is (reversed) Kleisli composition. That is, \( \text{parse} \) calls \( \text{parseF} \), and declares success only when the input can be parsed into a single tree.

5 Longest Balanced Prefix in a Fold

Recall our objective at the close of Section 2: to compute \( lbp = \text{maxBy size} \cdot \text{filtJust} \cdot \text{map parse} \cdot \text{inits} \) in a right fold, in order to obtain a faster algorithm using the scan lemma. Now that we have \( \text{parse} = \text{unwrapM} <\text{parseF} \) where \( \text{parseF} \) is a right fold, we perform some initial calculation whose purpose is to factor the postprocessing \( \text{unwrapM} \) out of the main computation:

\[
\text{maxBy size} \cdot \text{filtJust} \cdot \text{map parse} \cdot \text{inits}
\]

\[
\text{since } \text{parse} = \text{unwrapM} <\text{parseF}
\]

\[
\text{maxBy size} \cdot \text{filtJust} \cdot \text{map (unwrapM <\text{parseF})} \cdot \text{inits}
\]

\[
\text{since } (f <\text{c}) g x = f <\text{c} g x, \text{map fusion (backwards)}
\]

\[
\text{maxBy size} \cdot \text{filtJust} \cdot \text{map (unwrapM <\text{parseF})} \cdot \text{inits}
\]

\[
\text{since } \text{map parseF} \cdot \text{inits}
\]

\[
\text{unwrap} \cdot \text{maxBy (size \cdot \text{unwrap})} \cdot \text{filtJust} \cdot \text{map parseF} \cdot \text{inits} .
\]

In the penultimate step \( (\text{unwrapM} <\text{parseF}) \) is moved leftwards past \( \text{filtJust} \) and becomes \( \text{unwrap} :: \text{Forest} \rightarrow \text{Tree} \), defined by:

\[
\text{unwrap}[t] = t
\]

\[
\text{unwrap} = \text{Nul} .
\]

Recall that \( \text{inits} = \text{foldr} (\lambda x xss \rightarrow [:\text{map (x:) xss}]) [[]]. \) The aim now is to fuse \( \text{map parseF}, \text{filtJust}, \) and \( \text{maxBy (size \cdot \text{unwrap})} \) with \( \text{inits} \).

By Theorem 2, to fuse \( \text{map parseF} \) with \( \text{inits} \), we need to construct \( g \) that meets the fusion condition:

\[
\text{map parseF} ([]:\text{map (x:) xss}) = g x (\text{map parseF} xss) .
\]

Now that we know that \( \text{parseF} \) is a fold, the calculation goes:

\[
\text{map parseF} ([]:\text{map (x:) xss})
\]

\[
= \{ \text{definitions of map and parseF} \}
\]

\[
\text{Just [Nul]} : \text{map (parseF \cdot (x:)) xss}
\]

\[
= \{ \text{the foldr definition of parseF} \}
\]

\[
\text{Just [Nul]} : \text{map (\lambda ts \rightarrow parseF ts \gg \text{stepM} x) xss} = \{ \text{map-fusion (backwards)} \}
\]

\[
\text{Just [Nul]} : \text{map (\gg \text{stepM} x) (map parseF xss)} .
\]

Therefore we have
map parseF ∙ inits :: String → [Maybe Forest]
map parseF ∙ inits =
foldr (λx tss → Just [Nul]) ∙ map (≥ stepM x) ∙ tss) [Just [Nul]] .

Next, we fuse filtJust with map parseF ∙ inits by Theorem 2. After some calculations, we get:

filtJust ∙ map parseF ∙ inits :: String → [Forest]
filtJust ∙ map parseF ∙ inits = foldr (λx tss → Just [Nul]) ∙ extend x tss) [Nul]] ,
where extend ‘ (‘ tss = map (Nul:) ∙ tss
extend ‘ (’ tss = [(Bin t u : ts) | (t : u : ts) ← tss] .

After the fusion we need not keep the Nothing entries in the fold; the computation returns a collection of forests. If the next character is ‘)’, we append Nul to every forest. If the next entry is ‘(‘, we choose those forests having at least two trees, and combine them — the list comprehension keeps only the forests that match the pattern (t : u : ts) and throws away those do not. Note that [Nul], to which the empty string is parsed, is always added to the collection of forests.

To think about how to deal with unwrap ∙ maxBy (size ∙ unwrap), we consider an example. Figure 1 shows the results of map parseF and filtJust for prefixes of "( ) ( ) ".

Figure 1: Results of parseF and filtJust for prefixes of "( ) ( ) ".

map parseF ∙ inits :: String → [Maybe Forest]
map parseF ∙ inits =
foldr (λx tss → Just [Nul]) ∙ map (≥ stepM x) ∙ tss) [Just [Nul]] .

Next, we fuse filtJust with map parseF ∙ inits by Theorem 2. After some calculations, we get:

filtJust ∙ map parseF ∙ inits :: String → [Forest]
filtJust ∙ map parseF ∙ inits = foldr (λx tss → Just [Nul]) ∙ extend x tss) [Nul]] ,
where extend ‘ (‘ tss = map (Nul:) ∙ tss
extend ‘ (’ tss = [(Bin t u : ts) | (t : u : ts) ← tss] .

After the fusion we need not keep the Nothing entries in the fold; the computation returns a collection of forests. If the next character is ‘)’, we append Nul to every forest. If the next entry is ‘(‘, we choose those forests having at least two trees, and combine them — the list comprehension keeps only the forests that match the pattern (t : u : ts) and throws away those do not. Note that [Nul], to which the empty string is parsed, is always added to the collection of forests.

To think about how to deal with unwrap ∙ maxBy (size ∙ unwrap), we consider an example. Figure 1 shows the results of map parseF and filtJust for prefixes of "( ) ( ) ", where Just, Nul, and Bin are respectively abbreviated to J, N, and B. The function maxBy (size ∙ unwrap) chooses between [N] and [B N N], the two parses resulting in single trees, and returns [B N N]. However, notice that B N N is also the head of [B N N, B N N], the last forest returned by filtJust. In general, the largest singleton parse tree will also present in the head of the last forest returned by filtJust ∙ map parseF ∙ inits. One can intuitively see why: if we print them both, the former is a prefix of the latter. Therefore, unwrap ∙ maxBy (size ∙ unwrap) can be replaced by head ∙ last.

To fuse last with filtJust ∙ map parseF ∙ inits by Theorem 2, we need to construct a function step that satisfies the fusion condition

last ([Nul]: extend x tss) = step x (last tss) ,

where tss is a non-empty list of forests. The case when x = ‘)’ is easy — choosing step ‘)’ ts = Nul: ts will do the job. For the case when x = ‘(‘ we need to analyse the result of last tss, and use the property that forests in tss are ordered in ascending lengths.

a) If last tss = [t], a forest having only one tree, there are no forest in tss that contains two or more trees. Therefore extend ‘ (‘ tss returns an empty list, and last ([Nul]: extend ‘ (‘ tss) = [Nul].
b) Otherwise, extend ‘ (‘ tss would not be empty, and last ([Nul]: extend x tss) = last (extend x tss). We may then combine the first two trees, as extend would do.
In summary, we have

\[
\text{last} \cdot \text{filtJust} \cdot \text{map parseF} \cdot \text{inits} :: \text{String} \to \text{Forest} \\
\text{last} \cdot \text{filtJust} \cdot \text{map parseF} \cdot \text{inits} = \text{foldr} \text{ step} \ [\text{Nul}] , \\
\text{where } \text{step } '(': \text{ts} = \text{Nul} : \text{ts} \\
\text{step } '(': [\text{t}] = ([\text{Nul}]) \\
\text{step } '(': (t : u : \text{ts}) = \text{Bin } t u : \text{ts} ,
\]

which is now a total function on strings of parentheses.

The function derived above turns out to be \( \text{prF}^{-1} \) with one additional case (\( \text{step } '(': [\text{t}] = ([\text{Nul}]) \)). What we have done in this section can be seen as justifying this extra case (which is a result of case (1) in the fusion of \( \text{last} \)), which is not as trivial as one might think.

6 wrapping up

We can finally resume the main derivation in Section 2:

\[
\text{maxBy size} \cdot \text{map } (\text{maxBy size} \cdot \text{filtJust} \cdot \text{map parse} \cdot \text{inits}) \cdot \text{tails} \\
= [\text{Section 5: lbp = head} \cdot \text{foldr step} \ [\text{Nul}]] \\
\text{maxBy size} \cdot \text{map } (\text{head} \cdot \text{foldr step} \ [\text{Nul}]) \cdot \text{tails} \\
= [\text{map-fusion reversed, Lemma 1}] \\
\text{maxBy size} \cdot \text{map head} \cdot \text{scanr step} \ [\text{Nul}] .
\]

We have therefore derived:

\[
\text{lbs} :: \text{String} \to \text{Tree} \\
\text{lbs} = \text{maxBy size} \cdot \text{map head} \cdot \text{scanr step} \ [\text{Nul}] ,
\]

where \( \text{step} \) is as defined in the end of Section 5. To avoid recomputing the sizes in \( \text{maxBy size} \), we can annotate each tree by its size: letting \( \text{Forest} = [(\text{Tree}, \text{Int})] \), resulting in an algorithm that runs in linear-time:

\[
\text{lbs} :: \text{String} \to \text{Tree} \\
\text{lbs} = \text{fst} \cdot \text{maxBy size} \cdot \text{map head} \cdot \text{scanr step} \ [(\text{Nul},0)] , \\
\text{where } \text{step } '(': \text{ts} = (\text{Nul},0) : \text{ts} \\
\text{step } '(': [\text{t}] = ([\text{Nul},0]) \\
\text{step } '(': (t : u : \text{ts}) = (\text{Bin } t u, 2 + m + n) : \text{ts} .
\]

Finally, the size-only version can be obtained by fusing \( \text{size} \) into \( \text{lbs} \). It turns out that we do not need to keep the actual trees, but only their sizes — \( \text{Forest} = [\text{Int}] \):

\[
\text{lbsl} :: \text{String} \to \text{Int} \\
\text{lbsl} = \text{maximum} \cdot \text{map head} \cdot \text{scanr step} \ [0] , \\
\text{where } \text{step } '(': \text{ts} = 0 : \text{ts} \\
\text{step } '(': [\text{t}] = [0] \\
\text{step } '(': (m : n : \text{ts}) = (2 + m + n) : \text{ts} .
\]

We ran some simple experiments to measure the efficiency of the algorithm. The test machine was a laptop computer with a Apple M1 chip (8 core, 3.2GHz) and 16GB RAM. We ran \( \text{lbs} \) on randomly generated inputs containing 1, 2, 4, 6, 8, and 10 million parentheses, and measured the user times. The results, shown in Figure 2, confirmed the linear-time behaviour.
7 Conclusions and Discussions

So we have derived a linear-time algorithm for solving the problem. We find it an interesting journey because it relates two techniques: prefix-suffix decomposition for solving segment problems, and the converse-of-a-function theorem for program inversion.

In Section 3 we generalised from trees to forests. Generalisations are common when applying the converse-of-a-function theorem. It was observed that the trees in a forest are those along the left spine of the final tree, therefore such a generalisation is referred to as switching to a “spine representation” [Mu and Bird, 2003].

What we derived in Section 4 and 5 is a compacted form of shift-reduce parsing, where the input is processed right-to-left. The forest serves as the stack, but we do not need to push the parser state to the stack, as is done in shift-reduce parsing. If we were to process the input in the more conventional left-to-right order, the corresponding grammar would be $S \rightarrow \epsilon \mid S (S)$. It is an SLR(1) grammar whose parse table contains 5 states. Our program is much simpler. A possible reason is that consecutive shifting and reducing are condensed into one step. It is likely that parsing SLR(1) languages can be done in a fold. The relationship between LR parsing and the converse-of-a-function theorem awaits further investigation.

There are certainly other ways to solve the problem. For example, one may interpret a '(' as a $-1$, and a ')' as a $+1$. A left-partially balanced string would be a list whose right-to-left running sum is never negative. One may then apply the method in Zantema [1992] to find the longest such prefix for each suffix. The result will be an algorithm that maintains the sum in a loop — an approach that might be more commonly adopted by imperative programmers. The problem can also be seen as an instance of maximum-marking problems — choosing elements in a data structure that meet a given criteria while maximising a cost function — to which methods of Sasano et al. [2001] can be applied.

Acknowledgements The problem was suggested by Yi-Chia Chen. The authors would like to thank our colleagues in the PLFM group in IIS, Academia Sinica, in particular Hsiang-Shang ‘Josh’ Ko, Liang-Ting Chen, and Ting-Yan Lai, for valuable discussions. Also thanks to Chung-Chieh Shan and Kim-Ee Yeoh for their advice on earlier drafts of this paper. We are grateful to the reviewers of previous versions of this article, who gave detailed and constructive criticisms that helped a lot in improving this work.
