Introduction
A history of ventricular preexcitation conditions is disqualifying from service in the United States Navy. Between 0.1% and 0.3% of the population have elements of electrocardiographic preexcitation, with these conditions being managed based on the presence or absence of symptoms. A diagnosis of Wolff-Parkinson-White syndrome is established when patients with electrocardiographic preexcitation develop symptoms of palpitations or presyncope. Because the risk of sudden cardiac death in these patients is estimated to be 4% over a lifetime and because of the necessity for sailors to spend prolonged periods in medically austere environments, these conditions typically prohibit military service.

Fasciculoventricular pathway (FVP) is a very rare form of preexcitation resulting from an accessory connection between either the bundle of His or the fascicles and the ventricle. Patients with FVP demonstrate ventricular preexcitation on surface ECG but are not at risk of reciprocal tachycardias or sudden cardiac death. We present a case of a young sailor who presented with evidence of ventricular preexcitation on surface ECG (Figure 1). An electrophysiologic study was performed and these findings were deemed secondary to FVP. The sailor subsequently obtained a waiver of physical standards for continued special duty.

Case report
A 22-year-old male seaman on active duty in the US Navy submarine service presented with acute onset of right-sided chest discomfort during a physical readiness test. On examination, his vital signs were within normal limits and the chest discomfort was reproducible with palpation. An ECG showed normal sinus rhythm with a PR interval of 128 ms, delta waves in leads V4–V6 (Figure 1). Laboratory results and imaging were unremarkable. The pain resolved spontaneously without intervention. The patient was referred to the Undersea Medical Officer to assess his duty status.

Further evaluation included a transthoracic echocardiogram that did not show any evidence of structural heart disease. A stress echocardiogram was negative for ischemia. During that study, electrocardiographic delta waves were present at rest, persisted at peak activity, disappeared during early recovery, and returned shortly thereafter. An event monitor worn for 22 days showed sinus rhythm without any evidence of ectopy.

According to the physical standards governing service in the submarine force, a history of ventricular preexcitation conditions is considered disqualifying. The instruction specifically notes that a waiver to continue duty will be considered for personnel with a ventricular preexcitation ECG pattern who: “(a) Have never had a documented dysrhythmia, (b) Have never had a symptomatic episode consistent with a paroxysmal dysrhythmia (e.g. palpitations, dizziness, chest pain, dyspnea, loss of consciousness), and (c) Have been found to be at extremely low risk for a future event as determined by a cardiologist in conjunction with electrophysiologic study if indicated.”

Given that the patient’s history was not clearly consistent with Wolff-Parkinson-White syndrome as well as his desire to return to duty, an electrophysiological study was obtained for identification of any potentially arrhythmogenic substrate and further risk stratification of the ventricular preexcitation syndrome.

Baseline measurements included a sinus cycle length of 780 ms, PR of 125 ms, QRS of 120 ms, and QT of 380 ms. A-H interval was 47 ms. H-V interval was 15 ms, providing A-H interval while the H-V interval remained constant.
Isoproterenol was given. Para-Hisian pacing as outlined by Hirao and colleagues\(^7\) was performed and yielded a nodal response. There was no change in atrial activation sequence during these maneuvers, suggesting the absence of an accessory pathway connecting the atrium to the ventricle.

With single atrial premature beats, the accessory pathway blocked at 300/240 ms. Aggressive stimulation at 300/200/200 ms resulted in block at the AV node without any echo beats. Burst pacing from the atria and the ventricle did not reveal any inducible tachycardia. Anterograde effective refractory period of the accessory pathway was observed at 250 ms. Atrial fibrillation was induced and the shortest R-R interval was 280 ms, above the interval concerning for potentially malignant arrhythmia.

All findings of the electrophysiological study were consistent with a diagnosis of FVP. No ablation was performed. Although the patient’s presentation could have potentially disqualified him from continued submarine service, a special duty waiver was submitted on his behalf. The waiver was granted because of the careful elucidation of his conducting system in the electrophysiological study. At 1 year follow-up, the patient remains asymptomatic and as a newly qualified submariner, he is a productive member of his boat’s crew.

**Discussion**

FVP is very rare, occurring in 1.2% to 5.1% of patients with symptomatic preexcitation.\(^8\)\(^-\)\(^11\) No data have been published or presented regarding the prevalence in patients without symptoms. Surface ECG alone is insufficient to differentiate between typical atrioventricular accessory pathways and FVP.\(^12\) Presence of FVP is confirmed in a patient with preexcitation by observing prolongation of the A-H interval without a change in H-V interval during incremental or programmed atrial stimulation and fixed preexcitation with decremental AV node conduction. (Figure 2).\(^13\)\(^,\)\(^14\) These subnodal bypass tracts have not been found to participate in circus movement supraventricular tachycardias and their precarious anatomic location would confer high risk of irreversible conduction system damage during ablation. Thus, no intervention is recommended.
In this case, it was necessary to obtain more information regarding presence of potentially arrhythmogenic substrate in order to meet US Navy physical standards for submarine duty, but there is evidence to support invasive testing in a broader population with preexcitation. Recent American College of Cardiology/American Heart Association/Heart Rhythm Society guidelines suggest that existing evidence in the literature supports risk stratification with an electrophysiological study in certain circumstances, even in the absence of symptoms. Most importantly, data from the largest registry of patients with preexcitation syndromes showed that malignant arrhythmias correlate more with the electrophysiological properties of the accessory pathway than with the presence or absence of symptoms. Specifically, Pappone and colleagues identified inducible atrioventricular reentrant tachycardia triggering atrial fibrillation and short accessory pathway effective refractory period (less than 240 ms) as risk factors for sudden cardiac death. Both findings were absent in our patient’s evaluation.

**Conclusion**

What has previously been regarded as an electrocardiographic curiosity could have had potentially serious consequences for this patient’s livelihood and adversely impacted US Navy submarine force operational readiness. Instead, the electrophysiological study facilitated the diagnosis of FVP, allowed for adequate risk stratification for malignant arrhythmia and sudden cardiac death, and ultimately led to our patient’s return to duty.
