Abstract

*Rhodiola rosea* L. (*R. rosea*) is an adaptogenic plant increasing body resistance to stress. Its efficacy has been evidenced mainly in chronic stress models, data concerning its effect in acute stress and underlying mechanisms being scarce. The objective was to investigate the effect of repeated doses of a *R. rosea* hydroethanolic root extract (HRE) on hypothalamic pituitary adrenal response in a murine model of acute mild stress and also the mechanisms involved. Stress response was measured in Balb/c mice having received by gavage HRE (5 g/kg) or vehicle daily for 2 weeks before being submitted to an acute mild stress protocol (open-field test then elevated plus maze). Corticosterone was measured in plasma from mandibular vein blood drawn before and 30, 60, and 90 min after initiation of the stress protocol. Mice were sacrificed at 90 min, and the hippocampus, prefrontal cortex, and amygdala were excised for high-frequency RT-PCR gene expression analysis. At 30 min after acute mild stress induction, corticosterone level in mice having received the HRE was lower than in control mice and comparable to that in nonstressed mice in the HRE group. HRE administration induced brain structure-dependent changes in expression of several stress-responsive genes implicated in neuronal structure, HPA axis activation, and circadian rhythm. In the acute mild stress model used, *R. rosea* HRE decreased corticosterone level and increased expression of stress-responsive genes, especially in the hippocampus and prefrontal cortex. These findings suggest that *R. rosea* HRE could be of value for modulating reactivity to acute mild stress.

Keywords

acute mild stress, circadian rhythm, corticosterone, nutritional supplementation, rhodiola

INTRODUCTION

Stress is the physiological reaction to environmental threats or pressure and can be self-driven or of external origin (Angeleescu, Edwards, Seifritz, & Kasper, 2018). It is manifested by a wide variety of physical and psychological symptoms. If persistent and left untreated, stress can result in serious health problems including burnout, depression, post-traumatic stress disorder, anxiety, and cardiovascular, gastrointestinal, neurological, and musculoskeletal diseases. Stress appears to be a particular problem in our modern society. Work-related stress is experienced by all sections of society, being estimated to affect 22% of the European workforce (Milczarek & Gonzales, 2009). The World Health Organization has called stress “the health epidemic of the 21st century,” recognizing its substantial impact on personal life and also its social and economic consequences (Angeleescu et al., 2018; Subhani et al., 2018).

Stress management strategies include nonpharmacological approaches, such as cognitive behavioral therapy and relaxation, but recourse to pharmacological treatment is standard if stress and its symptoms become harmful. Anxiolytics and antidepressants, associated with known risks of adverse effects and dependency, are generally indicated for more severe situations. Several plants, including chamomile, melissa, and rhodiola, have been shown to be valuable for managing stress and its consequences, with fewer adverse effects and a lower risk of dependency (Sarris, McIntyre, & Camfield, 2013). *Rhodiola rosea* L. (rosenroot or golden root), manifesting adaptogenic properties, is among those most widely used (Angeleescu et al., 2018; Kasper & Dienel, 2017). Extracts of adaptogenic plants can normalize body functions and reinforce systems compromised by stress (Angeleescu et al., 2018). They have no specific pharmacological properties and act by increasing resistance to a broad spectrum of adverse expressions of stress. Preclinical in vivo and ex vivo studies in animal models and experiments on cell lines have highlighted several biochemical and pharmacological stress-reducing properties of *R. rosea* extracts (Abidov, Crendal, Grachev, Seifulla, & Ziegenfuss, 2003; Olsson, von Scheele, & Panossian, 2009; Panossian, Hambardzumyan, Hovhanissyan, & Wikman, 2007; Panossian, Hovhannisyan, Abrahamyan, Gabrielyan, & Wikman, 2009). In clinical studies, various extracts of *R. rosea* were found to be effective and safe, improving mental work capacity, concentration, task performance, fatigue, burnout symptoms, and overall mood, besides reducing stress level and self-reported mild anxiety (Crophy, Banks, & Boyle, 2015; Darbinyan et al., 2000; Edwards, Heufelder, & Zimmermann, 2012; Kasper & Dienel, 2017; Panossian, Wikman, Kaur, & Asea, 2009; Punja, Shamelse, Olson, & Vohra, 2014). *R. rosea* was approved by the European Medicines Agency Committee on Herbal Medicinal Products for the indication “temporary relief of symptoms of stress such as fatigue and sensation of weakness” (EMA/HPMC, 2012).

Stress response typically begins with activation of the hypothalamus–pituitary–adrenal (HPA) axis, one of the main stress response pathways, and the production of corticosteroids (Angeleescu et al., 2018; Subhani et al., 2018). Acute or chronic stress produces characteristic changes in the HPA axis, including an increase in cortisol in humans and corticosterone in rodents, as well as a reduction in the sensitivity of the HPA axis to feedback down-regulation (Anghelescu et al., 2018; Panossian, Wikman, et al., 2009). Chronic stress results in persistent elevation of cortisol or corticosterone levels, which may lead to fatigue, depression, and other symptoms (Anghelescu et al., 2018). The reduction in stress-induced damage by *R. rosea* is characterized by a decrease in or the prevention of hormonal changes characteristic of stress, including cortisol or corticosterone release, as shown in humans suffering from chronic stress following administration of the standardized *R. rosea* root extract SHR-5 during 28 days (Olsson et al., 2009) and in rabbits subjected to acute stress after 7 days of SHR-5 administration (Panossian et al., 2007). HPA axis modulation by *R. rosea* extracts also involves the inhibition of stress-induced protein kinases and nitric oxide in animals (Panossian, Wikman, et al., 2009). The HPA axis is not the only target of *R. rosea*. For instance, *R. rosea* extracts stimulated energy metabolism in rodents via the activation of ATP synthesis in mitochondria (Abidov et al., 2003) and might protect against neurodegenerative brain diseases through antioxidative and anti-inflammatory mechanisms (Lee et al., 2013; Zhang, Zhu, Jin, Yan, & Chen, 2006).

Investigations of the molecular mechanisms underlying central corticosteroid action following a stress event led to the identification of genetic pathways and, in particular, stress-responsive genes (Hunter et al., 2016; Kohrt et al., 2016). Modification of target gene transcription, the so-called genomic action of corticosteroids, is therefore most likely one of the main mechanisms underlying corticosteroid action in the brain (Gray, Kogan, Marrocco, & McEwen, 2017). These genomic effects can occur within 15–30 min after the activation of corticosteroid receptors and may last for less than an hour or up to several days, depending on the duration of exposure to the hormone and the type of stress (Dong, Poellinger, Gustafsson, & Okret, 1988; Morsink, Joels, et al., 2006). These stress-responsive genes are divided into several functional classes according to their implication in energy metabolism, signal transduction, neuronal structure, vesicle dynamics, neurotransmitter catabolism or cell adhesion, their encoding of neurotrophic factors and their receptors, and their involvement in the regulation of glucocorticoid signaling (Andrus et al., 2012; Datson, Morsink, Meijer, & de Kloet, 2008; Datson et al., 2012; Hunter et al., 2016). The effects of *R. rosea* extracts on these stress-responsive genes are unknown. Furthermore, all the data on *R. rosea* reported so far have been obtained following intense stress, either acute or chronic. Characterizing the effects of *R. rosea* on the HPA axis and stress-responsive gene transcription under acute mild stress conditions would contribute to a better understanding of how extracts of this adaptogenic plant act to prevent the negative effects of stress.

The purpose of this study was therefore to evaluate, in a murine model of acute mild stress, the effects on the HPA axis of repeated administration of a hydroethanolic root extract (HRE) of *R. rosea*, phytochemically characterized by high-performance thin-layer chromatography (HPTLC) and ultra-high-performance liquid chromatography coupled with mass spectrometry (UHPLC-MS). Corticosterone...
secretion and stress-responsive gene expression were determined in the prefrontal cortex (PFC), amygdala, and hippocampus, the main structures implicated in stress management.

## 2 MATERIAL AND METHODS

### 2.1 Preparation of the *R. rosea* HRE

The *R. rosea* HRE was obtained according to the patented process WO2001056584A1 by crushing frozen fresh roots of *R. rosea* and leaching with 20%–70% (v/v) ethanol. The extract was then concentrated under reduced pressure to evaporate ethanol. The salidroside titer was adjusted within the range of 0.7–1.4 mg/ml by adding glycerin to the concentrated extract. The batch of HRE used in this study (16H321), containing 83% glycerin, had a salidroside content of 1.02 mg/ml and a dry drug: dry genuine extract ratio of 17:1. This glycerin-containing HRE corresponds to the standardized extract of *R. rosea* marketed in France under the brand name “Extrait de plante fraîche standardisé (EPS) R. rosea” (PiLeJe Laboratoire, France).

### 2.2 LC/MS analysis of the *R. rosea* HRE

UHPLC analysis was performed on an Ultimate 3000 RSCL UHPLC system (Thermo Fisher Scientific Inc., MA, USA) coupled to a quaternary rapid separation pump (Ultimate autosampler) and a rapid separation diode array detector. Compounds were separated on an Uptisphere Strategy C18 column (25 × 4.6 mm; 5 μm; Interchim, Montluçon, France), maintained at 40°C. The mobile phase was a mixture of 0.1% (v/v) formic acid in water (phase A) and 0.1% (v/v) formic acid in acetonitrile (phase B). The gradient of phase A was 100% (0 min), 80% (10 min), 73% (35 min), 0% (40–50 min), and 100% (51–60 min). The flow rate was 0.8 ml/min and the injection volume 10 μl. The UHPLC system was connected to an Orbitrap mass spectrometer (Thermo Fisher Scientific Inc., MA, USA) operating in negative electrospray ionization mode. Source operating conditions were as follows: 3 kV spray voltage for negative mode; 320°C heated capillary temperature; 400°C auxiliary gas temperature; sheath, sweep, and auxiliary gas (nitrogen) flow rate 60, 17.5, and 3.5 arbitrary units, respectively; and collision cell voltage between 20 and 50 eV. Full scan data were obtained at a resolution of 35,000 whereas MS² data were obtained at a resolution of 17,500. Data were processed using Xcalibur software (Thermo Fisher Scientific Inc., MA, USA).

The constituents of the *R. rosea* HRE were identified according to their retention times and mass spectral data and by comparison with authentic standards, if available, or otherwise with published data.

### 2.3 HPTLC analysis of *R. rosea* HRE

Standards were diluted in methanol at a concentration of 0.5 mg/ml for rosavin and 0.1 mg/ml for salidroside (Sigma Aldrich, Saint Louis, USA). One mL of the *R. rosea* HRE (without added glycerol) was diluted in 3 ml of a mixture of 50% ethanol and water (50/50: v/v). The resultant solution was shaken and centrifuged for 3 min at 6,600 g. The supernatant solution was transferred into individual vials and then analyzed by HPTLC. HPTLC analysis was performed on 200 × 100 mm silica gel 60 F 254 HPTLC glass plates (Merck, Darmstadt, Germany), using a Camag HPTLC system (Muttenz, Switzerland) equipped with an Automatic TLC Sampler (ATS 4), an Automatic Developing Chamber ADC2 with humidity control, a TLC Visualizer, WinCATS software and for derivatization, a Chromatogram Immersion Device III, and a TLC Plate Heater III. Standard solutions and samples were applied as bands 8.0 mm wide, up to a 8.0 mm from the lower edge of the plate and 15 mm from the left and right edges. The space between bands was 11.3 mm, and each plate contained 16 tracks. The development distance was 70.0 mm from the lower edge of the plate. The temperature within the developing chamber was set at 21°C and the relative humidity at 37%. The mobile phase was a solution of ethyl acetate, water, formic acid, and methanol (volume ratio: 77/10/2/13). Derivatization was performed by dipping (speed: 5, time: 0) in a reagent comprising 10% sulfuric acid in methanol and heating at 100°C for 5 min. Plates were analyzed under UV at 366 nm.

### 2.4 Animals and experimental design

Seven-week-old male Balb/c mice, a highly stress-sensitive strain (Janvier, Le Genest-Saint-Isle, France), were housed under a normal 12-hr light/dark cycle (07 hr–19 hr) with food (AO4 diet; Safe, Augy, France) and water available ad libitum in a controlled environment (22 ± 1°C, 40% of humidity). The mice were handled daily for 1 week before the start of the experiment to minimize stress reactions to manipulation. During the following 2 weeks, they received each morning a supplement comprising either *R. rosea* HRE (a 5 g/kg solution containing 80% glycerin, i.e., 4 g/kg; test group, n = 8) or glycerin.

![FIGURE 1 Experimental protocol in adult Balb/c mice](Image)
alone (4 g/kg; control group, n = 8) administered by gavage using a VO105040 feeding probe (ECIMED, Boissy-Saint-Léger, France). The two groups received the same amount of glycerin. The volume of supplementation was adapted to the weight of each mouse. At the end of this period, the mice were subjected to an acute mild stress protocol and anxiety-like behavior was evaluated. Blood was drawn from the mandibular vein before initiation of the stress protocol (at t0 min) and then at t30 min and t60 min. Mice were sacrificed at t90 min, and brain structures (hippocampus, hypothalamus, and amygdala) and plasma were excised and frozen at −80°C (Figure 1).

### 2.5 Induction of acute mild stress

On the last day of supplement administration, half the mice in each group were subjected to acute mild stress. The stress protocol consisted in subjecting the mice to an open-field (OF) test for 10 min immediately followed by an elevated plus maze (EPM) test for 5 min (see the following sections for details; Figure 1). Experiments were performed in the morning, one hour after gavage, under conditions of dim light and low noise. Both tests induce mild stress in animals by subjecting them to anxiogenic conditions (Treit, Menard, & Royan, 1993).

### 2.6 Evaluation of anxiety-like behavior

Anxiety-like behavior was evaluated after induction of acute mild stress as previously reported by Dinel et al. (2011). Mouse behavior was videotaped and scored using “Smart” software (Noldus, Wageningen, Netherlands).

#### 2.6.1 OF test

Mice were exposed to an unfamiliar square (40 × 40 cm) OF from which escape was prevented by surrounding walls (16 cm high). The apparatus was virtually divided into 4 central squares defined as the central area (anxiogenic) and 12 squares along the walls, defined as the periphery. Each mouse was placed in the central area and allowed to freely explore the OF for 10 min. Parameters recorded to evaluate anxiety-like behavior comprised the number of entries into the central area and the percentage of time spent in this area (Dinel et al., 2011).

#### 2.6.2 EPM test

The EPM was a plus-shaped acryl maze with two opposing open arms (30 × 8 cm) and two opposing closed arms (30 × 8 × 15 cm) connected by a central platform (8 × 8 cm), elevated 120 cm above the floor. Each mouse was placed in the center of the maze facing an open arm, a situation that is highly anxiogenic. The test was performed over a period of 5 min. The number of arm entries and the percent of time spent in open arms were calculated to evaluate the basal level of anxiety. An entry was scored as such only when the mouse placed all its four limbs in any particular arm. A reduction in the percentage time spent in the open arms and the number of entries into these is considered as an index of anxiety-like behavior, independent of locomotor activity (Dinel et al., 2011).

### 2.7 Biochemical measurements

#### 2.7.1 Measurement of corticosterone

Corticosterone was measured in plasma before and 30, 60, and 90 min after initiation of the stress protocol, using a DetectX corticosterone immunoassay kit (Euromedex, Strasbourg, France) (Dinel, Joffre, et al., 2014).

#### 2.7.2 Assessment of RNA expression using Fluidigm microfluidic arrays

One microgram of total RNA was obtained from each brain area as described in Dinel et al. (Dinel, Andre, et al., 2014) and was reverse-transcribed with SuperScript III reverse transcriptase (Invitrogen, Cergy-Pontoise, France). Diluted cDNA (1.3 µl, 5 ng/µl) was added to DNA Binding Dye Sample Loading Reagent (Fluidigm), EvaGreen (Interchim, Montluçon, France), and Tris-EDTA (TE) buffer with low EDTA to constitute the Sample Mix plate. In the Assay Mix plate, 10 µl of primer pairs (100 µM) was added to the Assay Loading Reagent (Fluidigm) and TE buffer with low EDTA to a final concentration of 5 µM. After priming of the chip in the Integrated Fluidic Circuit Controller, Sample Mix (5 µl) and Assay Mix (5 µl) were loaded into the sample inlet wells. One well was filled with water as a contamination control. To verify specific target amplification and quantitative polymerase chain reaction (Q-PCR) process efficiencies, a control sample (mouse gDNA, Thermo Fisher, Waltham, USA) was treated, preamplified, and quantified in a control assay (RNasePTaqMan probe, Thermo Fisher) using the same process in the same plate at the same time. The expected value of cycle quantification was around 13. The chip was inserted into the IFC controller, in which 6.3 nl of Sample Mix and 0.7 nl of Assay Mix were blended. Real-time PCR was performed using the Biomark System (Fluidigm) on the GenoToul platform (Toulouse, France) with the following protocol: Thermal Mix at 50°C, 2 min; 70°C, 30 min; 25°C, 10 min, Uracl-DNA N-glycosylase (UNG) at 50°C, 2 min, Hot Start at 95°C, 10 min, PCR Cycle of 35 cycles at 95°C, 15 s; 60°C, 60 s and Melting curves (from 60°C to 95°C). Results were analyzed using the Fluidigm Real-Time PCR Analysis software v4.1.3. (San Francisco, USA) to control specific amplification for each primer. Then, the raw data of the qPCR were analyzed using GenEx software (MultiD analyses AB, Freising, Germany) in order to choose the best reference gene for normalizing mRNA expression and to measure the relative expression of each of the 93 genes analyzed in the group receiving the HRE and the control group. GAPDH was found to be the best reference gene in this experiment and was therefore used for normalization of gene expression.
2.8 | Statistical analysis

2.8.1 | Bivariate statistical analysis

All data were expressed as the mean value ± SEM (standard error of the mean). A p-value of 0.05 was considered as significant. Data were analyzed using a one-way ANOVA (one factor: supplementation) or a two-way ANOVA with supplementation (HRE, control), and stress (stress; no stress) as between factors followed by a Bonferroni post hoc analysis when interaction was significant (GraphPad software, La Jolla, US). Heatmaps were obtained using the Permut Matrix program (Caraux & Pinloche, 2005).

2.8.2 | Principal component analysis (PCA)

PCA was used to assess the gene expression pattern under stress conditions in the group receiving R. rosea HRE and the control group. The PCA is a dimension reduction technique that clusters data into principal components (PC) maximizing the variance of the data considered. These PCs are uncorrelated linear combinations of the initial variables which can be interpreted as a pattern. PCA generates factor loadings which reflect the correlation of each variable with the PC and attributes a PC score for each individual. We selected the number of components using the Cattell criterion. Statistical analyses were performed using the XLSTAT program (Addinsoft, Paris, France).

3 | RESULTS

3.1 | Phytochemical profile of R. rosea HRE

HPTLC analysis showed that R. rosea HRE contains salidroside and rosavin (Supplementary data, Fig. S1A). UHPLC-MS analysis confirmed the presence of these two compounds (peaks 7 and 15) (Fig. S1B and Table S1). Three monoterpenic glycosides corresponding to rhodiolosides E, B (or C) and rosinidin (peaks 13 and 24) and several phenylpropane derivatives, including rosarin and rosin, were identified (peaks 15–16 and 18). Five flavonoids were also detected: herbacetin, kaempferol, rhodamine, rhodopsin, and kaempferol-7-O-rhamnoside (peaks 22, 25, 21, 19, and 23, respectively).

3.2 | R. rosea HRE did not impact behavior in acute mild stress protocol

As expected, we did not observed any significant effect of the diet (glycerin or R. rosea HRE) on time spent in open arm in the EPM (Figure 2a) or on time spent in center area in the OF (Figure 2b).

3.3 | R. rosea HRE modulated corticosterone secretion consecutive to acute mild stress

Corticosterone was measured in plasma prepared from blood samples drawn before the induction of acute mild stress and 30, 60, and 90 min after the start of the stress protocol. At t0, mice having received R. rosea HRE exhibited a significantly higher plasma corticosterone level (110.8 ng/ml) than mice given the control supplement (glycerin alone, 31.31 ng/ml) (t = 2.789, p < .01; Figure 3a).

A t30, t60, and t90, R. rosea HRE induced a decrease in corticosterone secretion compared with the control (F (1,24) = 8.352, p < .01, Figure 3b; F (1,25) = 6.165, p < .05, Figure 3c; and F (1,26) = 5.954, p < .05, Figure 3d, respectively). At t30, we also observed a stress effect (F (1,24) = 6.391, p < .05, Figure 3b) and a stress × supplementation interaction (F (1,24) = 4.544, p < .01) indicating that 30 min after the induction of acute mild stress, administration of R. rosea HRE restored corticosterone secretion to the basal level.

**FIGURE 2** Anxiety-like behavior of adult mice subjected to acute mild stress having received a R. rosea HRE or glycerin (control) supplement for 2 weeks by daily gavage. (a) Time (in seconds) spent in the open arms of the elevated plus maze. (b) Time (in seconds) spent in the center area of the open-field. Data are presented as means ± SEM (n = 8 per group). HRE, hydroethanolic root extract.
3.4 | R. rosea HRE modulated stress-responsive gene expression in a structure-dependent manner

The expression of 93 genes implicated in stress reactivity was analyzed. Administration of R. rosea HRE modulated the pool of stress-responsive genes described by Datson et al. (2008, 2012), Andrus et al. (2012), and Kohrt et al. (2016). The genes modulated differed between the hippocampus, PFC, and amygdala and could be classified by function. All significant genes and results are presented in Tables 1 and 2.

In the hippocampus, 13 genes were significantly overexpressed after repeated administration of R. rosea HRE. These genes were implicated in signal transduction (CSNK2A1, F (1,22) = 4.694, p < .05; MAPK1, F (1,22) = 5.248, p < .05; SGK1, F (1,22) = 6.591, p < .05), neuronal structure (NEFL, F (1,22) = 8.870, p < .01; TUBB2, F (1,22) = 8.077, p < .01; PPP3CA, F (1,22) = 4.396, p < .05; PFN1, F (1,22) = 4.892, p < .05), oxidative stress (ATOX1, F (1,22) = 7.753, p < .05; APOE, F (1,22) = 4.450, p < .05; SIRT2, F (1,22) = 7.711, p < .05) and regulation of the HPA axis (LIS1, F (1,22) = 5.623, p < .05; DNCIC1, F (1,22) = 4.493, p < .05). PER1 expression, implicated in circadian rhythm, was also increased after HRE administration (F (1,22) = 7.774, p < .05). Stress affected the expression of 11 genes including NEFL, F (1,22) = 7.624, p < .05; PPP3CA, F (1,22) = 7.701, p < .05; PFN1 F (1,22) = 7.359, p < .05; SGK1, F (1,22) = 5.088, p < .05; DNCIC1, F (1,22) = 6.041, p < .05 and APOE, F (1,22) = 4.866, p < .05) that were also regulated by R. rosea HRE. The mitochondrial genes ND2 (F (1,22) = 12.17, p < .01) and ND4L (F (1,22) = 10.17, p < .01) were also upregulated by stress along with MAOA (F (1,22) = 10.68, p < .01), HSD11b (F (1,22) = 7.636, p < .05), and FKBP1a (F (1,22) = 6.701, p < .05), the expression of which is classically induced by chronic or acute stress.

In the PFC, acute mild stress affected only FKBP1a (F (1,16) = 16.10, p < .01). R. rosea HRE also increased the expression of genes implicated in neuronal structure (NEFL, F (1,16) = 16.14, p < .001; PPP3CA, F (1,16) = 19.07, p < .001; LIMK1, F (1,16) = 14.98, p < .01; GPM6A, F (1,16) = 8.791, p < .05), oxidative stress (SIRT2, F (1,16) = 9.914, p < .01; and GPX1, F (1,16) = 8.822, p < .05), HPA axis regulation (LIS1, F (1,16) = 12.96, p < .01; KIF5C, F (1,15) = 6.141, p < .05; FKBP1a, F (1,16) = 7.889, p < .05; BHLHB2, F (1,16) = 7.892, p < .05), and circadian rhythm (PER1, F (1,16) = 16.90, p < .001).

The amygdala was less responsive than the hippocampus and PFC to R. rosea HRE, only six genes being modulated by this supplement and/or stress. As in the other structures, PPP3CA, KIF5C, and PER1 were overexpressed following R. rosea HRE administration (F (1,18) = 8.174, p < .05; F (1,19) = 5.581, p < .05 and F (1,19) = 10.06, p < .01, respectively). Acute mild stress induced an increase in OD1 expression (F (1,19) = 5.575, p < .05). Interestingly, ND2 and ITPR1 expressions were similarly increased...

(Continues)
by HRE administration under stress conditions (stress × supplementation interaction \( F(1,19) = 4.399, p < .05; F(1,18) = 6.837, p < .05 \), respectively).

PCA of all genes studied in the hippocampus (Figure 4a), PFC (Figure 4b), and amygdala (Figure 4c) was performed to identify those contributing most to the observed differences between the treatment groups. Remarkably, PCA analysis showed clear separation of the variables: the first component (“F1”) explained 33.46%, 41.18%, and 26.46% of total variance in the hippocampus, PFC, and amygdala, respectively. Pattern 1 revealed that the genes studied were mostly upregulated in the hippocampus and PFC whereas their regulation was more heterogeneous in the amygdala. The second component (“F2”) explained 13.62%, 13.90%, and 17.60% of total variance in the hippocampus, PFC, and amygdala, respectively. This component could reveal a gene classification by functionality.

Phylogenetic analysis based on Pearson’s correlation was performed for the three brain structures studied (Figure 5). The heatmap generated demonstrated that gene regulation depends on the group considered (HRE-supplemented or control), especially as regards the PFC. However, we did not observe any real gene clusters.

4 | DISCUSSION
The objective of this study was to evaluate the effect on the HPA axis of chronic administration of a R. rosea HRE in a murine acute mild stress model by measuring corticosterone secretion and assessing cerebral expression of stress-responsive genes.

4.1 | R. rosea HRE decreased stress-induced corticosterone secretion
In the acute mild stress model used in this study, Balb/c mice were consecutively subjected to an OF and an EPM test. We chose to use Balb/c mice as studies have shown this strain to be highly stress-sensitive compared with other strains (Moloney, Dinan, & Cryan, 2015). Both tests used in this study induce stress in animals by placing them in anxiogenic environments: an open place in the OF test and open arms in the EPM test (Treit et al., 1993).

The basal level of corticosterone was higher in mice receiving R. rosea HRE than in control mice receiving a supplement containing glycerin alone. This difference might be explained by the organoleptic characteristics and higher viscosity of the HRE compared with glycerin alone, which could have created additional stress during administration of these supplements (Hoggatt, Hoggatt, Honerlaw, & Pelus, 2010). Even if the percentage of increase was important, the level of corticosterone in mice having received the R. Rosea HRE was far below levels obtained after a stress, even in low reactive mice (Mattos et al., 2013). Moreover, we did not observe any behavioral difference in anxiety-like tests between glycerin- and R. Rosea HRE-treated mice.

Thirty minutes after acute mild stress induction, control mice presented, as expected, an increase in corticosterone secretion, whereas mice receiving R. rosea HRE did not. At t60 and t90, the percentage corticosterone increase was comparable between stress-free and stressed mice. We hypothesize that the effect of experimentally induced acute mild stress was masked by that of gavage. We nevertheless observed that at both times, mice having received R. rosea HRE presented a lower percentage increase in corticosterone as compared to the control group. This result implies that administration of R. rosea HRE resulted in better regulation of stress homeostasis, characterized by more effective control of corticosterone increase that probably led to more efficient restoration of corticosterone level to the basal value.

At the intracellular level, high corticosterone levels impact the balance between trophic and atrophic factors within neurons (Liu et al., 2017). For instance, glucocorticoids have been shown to inhibit cell proliferation in the dentate gyrus by reducing the proliferation of granule cell precursors (Gould & Tanapat, 1999; Saaltink & Vreugdenhil, 2014). Moreover, chronic stress results in persistent inhibition of granule cell production and changes in the structure of the dentate gyrus, raising the possibility that stress alters hippocampal function through this mechanism (Gould & Tanapat, 1999). By preventing the substantial increase in corticosterone level, R. rosea extracts could prevent this negative impact of corticosteroids. Our results confirm those of previous studies demonstrating the impact of R. rosea extracts on inhibition of the HPA axis, as illustrated notably by the serum level of corticosteroids in rats (Cifani...

et al., 2010; Xia, Li, Wang, Wang, & Wang, 2016). The antistress properties of *R. rosea* extracts have been attributed to their interference with both the HPA axis and the sympathoadrenal system (Panossian, Hovhanisyan, et al., 2009; Panossian & Wagner, 2005; Panossian, Wikman, et al., 2009; Panossian, Wikman, & Wagner, 1999). However, all these results were obtained in animals subjected to intense acute or chronic stress. In this study, we demonstrated for the first time that a specific *R. rosea* extract affects HPA axis reactivity even under conditions of mild stress of short duration. The dampening of corticosterone secretion could be due to a decrease in stress reactivity amplitude or to better control of the glucocorticoid pathway.

### 4.2 *R. rosea* HRE upregulated the expression of functional stress-responsive genes

One of the main mechanisms of action of corticosteroids in the brain is their genomic effect, resulting in modification of target gene transcription. Corticosteroid-mediated transcriptional changes within the brain have been studied by means of large-scale gene expression profiling (Datson et al., 2008, 2012; Hunter et al., 2016; Kohrt et al., 2016). The resulting gene expression profile showed a highly dynamic transcriptional response to glucocorticoid receptor activation throughout a specific time window, shifting from exclusively down-regulation of genes 1 hr after glucocorticoid receptor activation to both up- and down-regulation after 3 hr (Morsink, Steenbergen, et al., 2006). We investigated the impact of *R. rosea* HRE, 1h30 after the induction of acute mild stress, on the expression of stress-responsive genes (Datson et al., 2008, 2012; Hunter et al., 2016) in the PFC and amygdala, structures involved in the regulation of stress, as well as in the hippocampus, a medial temporal lobe structure implicated in the formation of stable memories and highly susceptible to stress (Kim & Diamond, 2002).

Interestingly, most genes modulated in the PFC, amygdala, and hippocampus by *R. rosea* HRE belong to four main functional groups of genes implicated in the functioning of neuronal structures, glucocorticoid signaling, circadian rhythm, and mood regulation, respectively.

Supplementation with *R. rosea* HRE upregulated genes coding for structural components of the cytoskeleton, such as beta-tubulin (TUBB2) and neurofilament light polypeptide (NEFL), genes mediating neurite outgrowth, including glycoprotein M6A (GPM6A) (Alfonso, Fernandez, Cooper, Flugge, & Frasch, 2005), as well as genes specifically involved in the dynamics of the actin cytoskeleton of neurons, calcineurin subunit A (PPP3CA), and profilin 1 (PFN1). Genes affecting the actin cytoskeleton were modulated by the HRE in all three brain structures studied, but acute mild stress affected their expression only in the hippocampus. The actin cytoskeleton is involved in the morphology of dendritic spines, and changes in actin cytoskeletal configurations have been postulated to influence long-term potentiation, affecting synaptic transmission (Meng et al., 2002; Smart & Halpain, 2000). Under stress, these mechanisms are dysregulated and the connectivity between the various brain structures is impaired (Christoffel, Golden, & Russo, 2011). Several studies have demonstrated that stress induces adverse changes in the morphology and strength of hippocampal excitatory synapses, inducing a generalized atrophy of dendrites and spines in the PFC (Goldwater et al., 2009; Sandi et al., 2003; Stewart et al., 2005; Wellman, 2001). By upregulating genes implicated in neuronal structure genes, *R. rosea* HRE might prevent adverse changes in synaptic plasticity and consequently functional disorders, such as those observed in pathological behaviors or depression.

**FIGURE 4** Graphic representation, defined by the first two principal components (F1 and F2), of the Principal Component Analysis (PCA) of gene expression measured by RT-PCR in the hippocampus (a), prefrontal cortex (b), and amygdala (c) of adult mice having received a *R. rosea* HRE or glycerin (control) supplement by daily gavage for 2 weeks before the induction of acute mild stress. HRE, hydroethanolic root extract

**FIGURE 5** Phylogenic relationship based on Pearson’s correlation in the hippocampus (a), prefrontal cortex (b), and amygdala (c) of adult mice having received a *R. rosea* HRE or glycerin (control) supplement for 2 weeks by daily gavage before the induction of acute mild stress. The genes highlighted were modulated by stress, HRE supplementation, or interaction. HRE, hydroethanolic root extract.
R. rosea HRE also had an impact on the glucocorticoid signaling pathway. Glucocorticoids have been shown to modulate motor activity and axonal transport by regulating transcription levels of dynen cytoplasmic 1 intermediate chain 1 accessory subunit polypeptide (DNCIC1), lissencephaly protein 1 (LIS1), and 5c (KIF5C), a member of the kinesin family (Datson, van der Perk, de Kloet, & Vreugdenhil, 2001; Jimenez-Mateos, Wandsell, Reiner, Avila, & Gonzalez-Billault, 2005; Kanai et al., 2000; Morsink, Steenbergen, et al., 2006). In our model, R. rosea HRE upregulated the expression of DNCIC1, LIS1, and KIF5C in both the PFC and the hippocampus. KIF5C expression was also upregulated in the amygdala, after HRE supplementation. Acute mild stress affected DNCIC1 expression only in the hippocampus. This modulation of gene expression could act as a primer of the glucocorticoid signaling system. In particular, by upregulating these genes, R. rosea HRE could modify glucocorticoid receptor trafficking (Harrell et al., 2004), thereby modulating glucocorticoid receptor translocation and consequently glucocorticoid receptor signaling. Our results showed that R. rosea HRE modulated glucocorticoid receptor signaling by changing the expression of genes affecting receptor levels and receptor binding affinity preferentially in the PFC and hippocampus. Moreover, FKBP1a, a glucocorticoid receptor cochaperone affecting the binding affinity of ligands to glucocorticoid receptors (Kovacs, Cohen, & Yao, 2005; Kovacs, Murphy, et al., 2005; Riggs et al., 2004; Sakisaka, Merloor, Matteson, Plutner, & Balch, 2002; Wochnik et al., 2005) was upregulated by acute mild stress in the PFC and hippocampus but its expression was also affected by R. rosea HRE in the PFC. In our model, R. rosea HRE also induced in the hippocampus an upregulation of CSNK2A1 and MAPK1 expression, two genes involved in glucocorticoid signal transduction. Previous studies showed that acute administration of glucocorticoids downregulates CSNK2A1 and MAPK1 expression. To conclude, in the model of acute mild stress used, R. rosea HRE decreased corticosterone levels and increased the expression of stress-responsive genes, especially in the hippocampus and PFC. Most of the genes affected are implicated in neuronal structure and could impact synaptic transmission and plasticity as well as the glucocorticoid signaling regulation pathway. This upregulation by R. rosea HRE is associated with damping of corticosterone secretion and a faster return to the basal profile. This result could be explained by a greater efficacy of HPA axis feedback with a more appropriate adaptation of the animals receiving R. rosea HRE to a new environment. Moreover, R. rosea extracts might modulate the circadian rhythm and potentially biological processes driven by the circadian clock. Complementary studies would be needed to reinforce these preliminary data. Mapping of the signaling pathways and transcription factors involved, both in cell cultures and in animal models, could help to decipher the impact of HRE extracts under stress conditions. The new data presented here nevertheless suggest that R. rosea HRE could be of value in modulating reactivity to acute mild stress.

CONFLICT OF INTEREST

This work was funded by Groupe PiLeJe. Financial support was provided to Sigma Clermont for the performance of the chromatographic analyses and to INRA/NutriBrain for the conduct of in vivo experiments (service provision). The specific roles of the authors including Isabelle Guinobert, Claude Blondeau, and Valérie Bardot from Groupe PiLeJe are articulated in the “author contributions” section.

ETHICAL STATEMENTS

Animal husbandry and experimental procedures were in accordance with the EU Directive 2010/63/EU for animal experiments and were...
approved by the national ethical committee for the care and use of animals (approval ID A13169).
